Abstract

Ground-based high-resolution spectroscopy (HRS) has detected numerous chemical species and atmospheric dynamics in exoplanets, most notably ultrahot Jupiters (UHJs). However, quantitative estimates on abundances have been challenging but are essential for accurate comparative characterization and to determine formation scenarios. In this work, we retrieve the atmospheres of six UHJs (WASP-76 b, MASCARA-4 b, MASCARA-2 b, WASP-121 b, HAT-P-70 b, and WASP-189 b) with ESPRESSO and HARPS-N/HARPS observations, exploring trends in eleven neutral species and dynamics. While Fe abundances agree well with stellar values, Mg, Ni, Cr, Mn, and V show more variation, highlighting the difficulty in using a single species as a proxy for metallicity. We find that Ca, Na, Ti, and TiO are underabundant, potentially due to ionization and/or nightside rain-out. Our retrievals also show that relative abundances between species are more robust, consistent with previous works. We perform spatially resolved and phase-resolved retrievals for WASP-76 b and WASP-121 b given their high signal-to-noise observations, and find the chemical abundances in each of the terminator regions are broadly consistent. We additionally constrain dynamics for our sample through Doppler shifts and broadening of the planetary signals during the primary eclipse, with median blueshifts between ~ 0.9 and 9.0 km s^{-1} due to day–night winds. Furthermore, we constrain spectroscopic masses for MASCARA-2 b and HAT-P-70 b consistent with their known upper limits, but we note that these may be biased due to degeneracies. This work highlights the importance of future HRS studies to further probe differences and trends between exoplanets.

1. Introduction

We are entering the era of comparative exoplanet atmosphere science, with a new generation of observatories probing the atmospheres of planets in ever-increasing detail to determine the similarities of these worlds to each other and our own solar system. Recently, ground-based facilities capable of observing exoplanets at very high spectral resolution ($R \gtrsim 25,000$) (e.g., Mayor et al. 2003; Jurgenson et al. 2016; Pepe et al. 2021) have allowed for unprecedented detail into the chemical inventory of exoplanets, most notably for ultrahot Jupiters with temperatures in excess of 2000 K. These strongly irradiated exoplanets are unique laboratories, which exhibit a wide range of chemistry and physics (e.g., Fortney et al. 2008; Parmentier et al. 2018), and are excellent targets to study planetary chemical composition, particularly of refractory species. The high-resolution observations allow us to resolve

many thousands of individual absorption lines in the planetary spectrum (see, e.g., Birkby 2018). The difference in the position and relative strength of the spectral lines between species allows us to unambiguously detect a range of atoms, molecules, and ions in the atmosphere. A wide range of chemical species has been observed in UHJs (e.g., Casasayas-Barris et al. 2018; Hoeijmakers et al. 2019; Seidel et al. 2019; Ben-Yami et al. 2020; Cont et al. 2021; Merritt et al. 2021; Kesseli et al. 2022; van Sluijs et al. 2023). In particular, gaseous Fe has been shown to be prevalent in a number of UHJs, under both primary and secondary eclipse observations (e.g., Hoeijmakers et al. 2018, 2020a; Nugroho et al. 2020; Pino et al. 2020; Yan et al. 2020; Casasayas-Barris et al. 2022; Kasper et al. 2023).

High-resolution observations of UHJs have also allowed us to explore winds present in their atmospheres. Global winds result in a Doppler shift and/or broadening of the overall spectrum due to the motion of the constituents of the planetary atmosphere toward or away from the observer, and can most clearly be constrained during the primary eclipse (e.g., Snellen et al. 2010; Louden & Wheatley 2015; Brogi et al. 2016).

For planets where only an upper mass limit was detected, we used a K_* value of 0.0.

^a MASCARA-2 b is also known as KELT-20 b.

These transit observations have shown that wind speeds of \sim kilometers per second are present in the upper atmospheres of these highly irradiated planets (e.g., Seidel et al. 2021; Langeveld et al. 2022), and allowed for theoretical studies of the circulation patterns (Tan & Komacek 2019). In addition, we have been able to explore variations of the spectra during the transit (Ehrenreich et al. 2020; Kesseli & Snellen 2021), and have shown that condensation, cloud formation on one side of the planet, and thermal asymmetries can result in shifts in the strength and position of spectral features as the transit progresses (e.g., Gandhi et al. 2022; Savel et al. 2022). The mechanisms that drive the speed and spatial distribution of the winds are influenced by atmospheric drag (e.g., Wardenier et al. 2021) and by magnetic fields (e.g., Beltz et al. 2022). Atmospheric winds are also coupled to the formation of clouds in the atmosphere (Komacek et al. 2022). Hence, the dynamics are important quantities for understanding the various processes within these planets as well as obtaining reliable chemical compositions.

Recently, retrievals of high-resolution spectra have given us the ability to quantitatively constrain on the chemical abundances of gaseous species in the atmospheres of hot and ultrahot Jupiters (Brogi et al. 2017; Gandhi et al. 2019; Line et al. 2021; Pelletier et al. 2021; Gibson et al. 2022). Such retrievals have become possible thanks to developments in likelihood-based approaches for high-resolution spectra (Brogi et al. 2017; Brogi & Line 2019; Gibson et al. 2020), and often explore many millions of models over a wide range in parameter space to fit the observations. The high-resolution modeling required for the retrievals requires significant computational power, but allows for quantitative estimates to be placed on the atmospheric constituents. The abundance constraints are the key to determining the refractory and volatile content of the atmosphere and thus understanding how

these planets formed and migrated to their current location close to their host star (e.g., Madhusudhan et al. 2014; Lothringer et al. 2021; Knierim et al. 2022).

Given the numerous recent high-precision observations of UHJ atmospheres, a key step is to be able to compare and contrast the chemical composition of these exoplanets in order to observe trends as well as to explore potential formation pathways. In this work, we perform high-resolution retrievals of terminator observations of six UHJs, and constrain eleven neutral atomic and molecular species expected to be prevalent in their atmospheres. Furthermore, we constrain the winds on the terminator of these UHJs through velocity shifts of the planetary signal and compare the trends across our sample. We use the optical observations obtained with the ESPRESSO and HARPS-N/HARPS spectrographs as shown in Table 1. Our sample of UHJs was chosen given their similar ~ 2200 – 2600 K equilibrium temperatures and the multiple species that are prominent in their atmosphere (e.g., Cabot et al. 2020; Merritt et al. 2021; Tabernero et al. 2021; Kesseli et al. 2022).

We retrieve the chemical species in the atmosphere using the HyDRA-H high-resolution retrieval models (Gandhi et al. 2019). We perform retrievals with chemical abundances of eleven species as free parameters: Fe, Mg, Ni, Cr, Mn, V, Ca, Ti, TiO, TiH, and Na. For this work, we do not retrieve ionic species in order to keep the retrievals computationally tractable and given that ionic species generally have more complex vertical chemical abundance profiles. For two of the planets in our survey, WASP-76 b and WASP-121 b, we perform additional phase-separated and spatially resolved retrievals with HyDRA-2D given the high signal-to-noise and high-resolution $R = 140,000$ ESPRESSO observations available (Gandhi et al. 2022). This allows us to further explore the variation of the chemical species and dynamics in the different regions of the terminator for these two planets.

The next section discusses the retrieval setup and data analysis, followed by the results and discussion where we explore the constraints on the atmospheric chemistry and dynamics. Finally, we present the concluding remarks in Section 4.

2. Methods

In this section, we discuss the modeling setup and data analysis. We use HyDRA-H and HyDRA-2D to perform the retrievals of the exoplanets in our survey (Gandhi et al. 2019, 2022). These models explore a wide range of compositions, temperature profiles, cloud and/or opacity decks, and wind speed distributions to characterize the atmosphere from ground-based high-resolution observations. We use primary eclipse observations with the ESPRESSO spectrograph on the Very Large Telescope (VLT; Pepe et al. 2021), HARPS-N spectrograph on the Telescopio Nazionale Galileo (TNG), and HARPS on La Silla (Mayor et al. 2003), which cover the optical wavelength range ($\sim 0.4\text{--}0.8\ \mu\text{m}$). Table 1 shows the system parameters for each of the planets in our survey and the observations we used. We discuss the retrieval setup, our target sample, and data analysis in further detail below.

2.1. Atmospheric Modeling and Retrieval Setup

We perform our retrievals for the six planets using HyDRA-H (Gandhi et al. 2019). Our setup assumes free parameters for the atmospheric chemistry (volume mixing ratio for each chemical species) and a vertically varying temperature profile. Our atmosphere is assumed to be H/He-rich, which is a valid assumption for these UHJs given the high temperatures will lead to substantial dissociation of H_2 in the photosphere (see, e.g., Parmentier et al. 2018; Gandhi et al. 2022).

To generate our model spectra for each of the exoplanets, we use the latest and most precise line lists to determine the line-by-line opacity from each of the spectrally relevant species in the atmosphere. The opacity for the atomic species is determined using the Kurucz line list (Kurucz & Bell 1995). The cross sections for the molecular species TiO and TiH are calculated using the TOTO (Tennyson et al. 2016; McKemmish et al. 2019) and MoLLIST (Burrows et al. 2005; Bernath 2020) line lists respectively. These high-temperature line lists are the most suitable to the high-resolution observations in our study given their accurately determined line positions. For each spectral line, we determine the broadening due to the temperature as well as pressure, which results in a Voigt line profile. The pressure broadening coefficients are calculated using the method of Sharp & Burrows (2007) and described in further detail in Gandhi et al. (2022) for atomic species, and Gandhi et al. (2020b) for the molecules. For each species, we determine the total cross section by summing the contributions from each of the lines, calculated between 0.33 and $50\ \mu\text{m}$ with a wavenumber spacing of $0.01\ \text{cm}^{-1}$. This corresponds to a spectral resolution of $R = 2.5 \times 10^6$ at $0.5\ \mu\text{m}$.

We additionally include the haze and opacity deck of the atmosphere into our retrieval as an additional source of absorption, which originates from any potential cloud condensation or haze (e.g., Gao & Powell 2021; Komacek et al. 2022) as well as other species with strong continuum-like opacity such as TiO or H- (e.g., Hubeny et al. 2003; Arcangeli et al. 2018; Parmentier et al. 2018; Gandhi et al. 2020c).

However, our high-resolution observations are generally more sensitive to higher altitudes above the regions with significant opacity (see, e.g., Gandhi et al. 2020a; Hood et al. 2020), but clouds and hazes can impact the spectra, and hence we include them into our retrieval to avoid any biases in the chemical abundances.

For each of the spectral models in our retrieval, we generate transmission spectra using numerical radiative transfer (e.g., Pinhas et al. 2018). We determine the temperature profile using the parameterization of Madhusudhan & Seager (2009), which uses 6 free parameters, and allows for noninverted, isothermal, and inverted profiles. We also include free parameters ΔK_p , ΔV_{sys} , and δV_{wind} into our retrieval, which are the deviation from the planet's known orbital velocity, deviation from the known systemic velocity and the full width half maximum of the wind profile of the atmosphere (see Gandhi et al. 2022, for further details). For each model, we generate spectra at a resolution of $R = 500,000$ in the wavelength range of the observations, and convolve to the instrumental resolution of $R = 140,000$ for ESPRESSO, and $R = 115,000$ for HARPS-N/HARPS.

We perform additional retrievals for WASP-76 b and WASP-121 b with HyDRA-2D (Gandhi et al. 2022), separating the regions of the terminator into a morning (leading) limb and an evening (trailing) limb, with separate chemical abundances, temperature profile, and opacity deck for each half of the terminator. This model has been demonstrated on the WASP-76 ESPRESSO observations, showing differing chemical, thermal, and opacity deck constraints between the two halves of the terminator. Previous work has shown that multi-dimensional retrievals are important for such hot exoplanets (e.g., Pluriel et al. 2022). Furthermore, we perform separate retrievals over the first and last parts of the transit, allowing us to determine the chemical variation across phases as well as across the terminator. This was possible due to the high-precision observations of these two systems available with ESPRESSO, and given that the regions of the atmosphere probed during the transit vary by $\gtrsim 30^\circ$ (Wardenier et al. 2022). For each half of the terminator, we calculate separate phase-dependent limb-darkening coefficients. The coefficients vary across the transit because the morning (or leading) terminator transits the brighter regions of the star during the first half of the transit and thus has a greater contribution, while the second half of the transit has a greater contribution from the evening (or trailing) side. We maintain ΔK_p , ΔV_{sys} , and δV_{wind} as shared parameters, which remain the same for both halves of the terminator. We perform the HyDRA-2D retrievals including only the species that were detected in the spatially homogeneous and phase-unresolved HyDRA-H retrievals of these planets in order to keep them computationally efficient. Further details on the setup of the retrievals can be found in Gandhi et al. (2022).

2.2. Target Sample

We retrieve the atmospheres of six UHJs with publicly available high-precision high-resolution observations of their terminators: WASP-76 b, MASCARA-4 b, MASCARA-2 b, WASP-121 b, HAT-P-70 b, and WASP-189 b. These ultrahot Jupiters have equilibrium temperatures ranging between ~ 2210 and $2640\ \text{K}$ (see Table 1), where numerous refractory species are expected to be gaseous (Lothringer et al. 2018). We used ESPRESSO observations for WASP-76 b, MASCARA-4 b,

and WASP-121 b; HARPS-N for MASCARA-2 b, and HAT-P-70 b; and a combination of HARPS and HARPS-N for WASP-189 b. These high-precision transit observations have previously been used to detect a range of species in the atmospheres of each of the planets, most notably Fe, and are detailed below.

The reduced WASP-76 b data were downloaded from the Data and Analysis Center for Exoplanets (DACE) database.¹² These data were originally published in Ehrenreich et al. (2020), which showed clear absorption of Fe but also variability in its signal with orbital phase, potentially due to rain-out of Fe and/or clouds (Gandhi et al. 2022; Savel et al. 2022). These ESPRESSO observations have also been used to detect numerous other atomic and ionic species in the atmosphere (Tabernero et al. 2021; Kesseli et al. 2022). The MASCARA-4 b transit observations were recently published in Zhang et al. (2022), showing numerous atoms and ions. The fully reduced 1D spectra of WASP-121 b from ESPRESSO and WASP-189 b from HARPS were downloaded from the ESO archive,¹³ while the HARPS-N spectra were downloaded from the TNG archives.¹⁴ The ESPRESSO observations of WASP-121 b (Borsa et al. 2021) added new detections to an already rich spectrum containing many neutral and ionized atoms from many different spectrographs (Hoeijmakers et al. 2020b; Ben-Yami et al. 2020; Cabot et al. 2020; Merritt et al. 2021). The HAT-P-70 b observations were originally published in Bello-Arufe et al. (2022), while WASP-189 b observations were published by Prinoth et al. (2022) and showed the first conclusive detection of TiO at high spectral resolution. Finally, the HARPS-N observations of MASCARA-2 b have been used in many previous studies (Casasayas-Barris et al. 2018, 2019; Nugroho et al. 2020; Stangret et al. 2020), also showing a large range of atoms and ions. These atomic detections were further confirmed in Hoeijmakers et al. (2020a) using the EXPRES spectrograph.

With the higher spectral resolution and signal-to-noise available from ESPRESSO/VLT, we chose to perform spatially resolved and phase-separated HyDRA-2D retrievals for both WASP-76 b and WASP-121 b. The phase ranges of the retrievals are given in Table 5. We leave out the phases near 0 to avoid interference with the Doppler shadow of the star, where the planetary signal and the stellar signal have the same velocity component and hence cannot be straightforwardly separated (see, e.g., Gandhi et al. 2022).

The observations of MASCARA-4 b are also obtained with the ESPRESSO spectrograph, but this target had strong stellar pulsations as well as Rossiter–McLaughlin (RM) effects, and thus we only perform spatially homogeneous retrievals for this planet. Due to the lower spectral resolution of HARPS-N and HARPS, we also only perform spatially homogeneous retrievals for the other targets. For MASCARA-2 b and HAT-P-70 b, only upper limits on the planetary masses are available, and hence we include the surface gravity of the planet, $\log(g)$, as an additional free parameter in our retrievals for these two planets. This parameter is necessary in order to avoid biases, as the atmospheric scale height is sensitive to the choice of surface gravity and hence planetary mass.

2.3. Data Analysis

We cleaned and processed all the data following the procedure of Gandhi et al. (2022). We corrected each spectrum for telluric absorption using molecfit (Smette et al. 2015), which has been shown to effectively remove contamination from H₂O and O₂ at visible wavelengths in all but the strongest absorption lines (Allart et al. 2017). We masked out any regions of the spectra where the transmission through Earth’s atmosphere was less than 20%, and hence the molecfit correction returned poor results. We perform the following cleaning steps for each transit observation separately (totaling 13 transits for the six planets). We shifted the spectra to the stellar rest frame using the barycentric velocity during each exposure, the stellar reflex motion (calculated using K_* from Table 1), and the systemic velocity (V_{sys} ; see Table 1). We performed a 5σ clipping and apply a Gaussian high-pass filter with a full width half maximum of 100 km s^{-1} to create highly uniform grids of spectra. We then interpolated the spectra onto a single wavelength grid for each night, created by averaging all the wavelengths together during each observation set. Finally, we divided each spectrum by the average out-of-transit spectrum to remove any contribution from the host star. Note that given the stability of fiber-fed spectrographs, such as ESPRESSO, we are able to model the tellurics and divide by the out-of-transit spectra. In general, other less-stable spectrographs and/or those that use infrared observations will typically require more complicated filtering, such as a principal component analysis.

The RM effect in combination with center-to-limb variations (CLV) create a residual structure in the cross correlation grid (often called the Doppler shadow), which could influence the results of our retrievals if not removed. Previous methods to correct the Doppler shadow have proven effective in regions where there is not an exact overlap between the shadow and the planet’s signal, but struggle to produce results clean enough to detect the planet’s signal when there is an exact overlap, especially for a cross correlation analysis (e.g., Casasayas-Barris et al. 2021, 2022). In addition, the planetary radius appears larger at these regions of overlap, and therefore we chose phase ranges that excluded spectra that had direct overlap with the Doppler shadow. For many of our targets, this contamination was limited to only a few spectra, and the majority of the phases are still included in the retrievals (see Table 5). Figure 1 shows cross correlation grids for each target and an Fe line list, revealing a clear signal in each exoplanet’s atmosphere.

We find that, for both MASCARA-4 b and WASP-189 b, while the Doppler shadow only directly overlaps with a small portion of the spectra, the rapid stellar rotation creates large wings of positive residuals around the Doppler shadow that bias our retrievals (see Figure 2). To correct the RM and CLV effects, we followed Yan & Henning (2018), Casasayas-Barris et al. (2021, 2022) and simulated stellar observations at 10 different limb-darkening angles and velocities across the stellar surface using the Spectroscopy Made Easy package (Valenti & Piskunov 1996). To create synthetic observation of the Doppler shadow, we divided the surfaces of the stars in $0.01 \times 0.01 R_*$ pieces and assigned each one a velocity based on the known $v \sin i$ and limb-darkening angles. We then combined all the spectra, excluding those that were covered by the planet at the time of each observation, and performed the same cleaning steps on the synthetic observations as we did on the data.

¹² <https://dace.unige.ch/dashboard/index.html>

¹³ <http://archive.eso.org/scienceportal/home>

¹⁴ <http://archives.ia2.inaf.it/tng/>

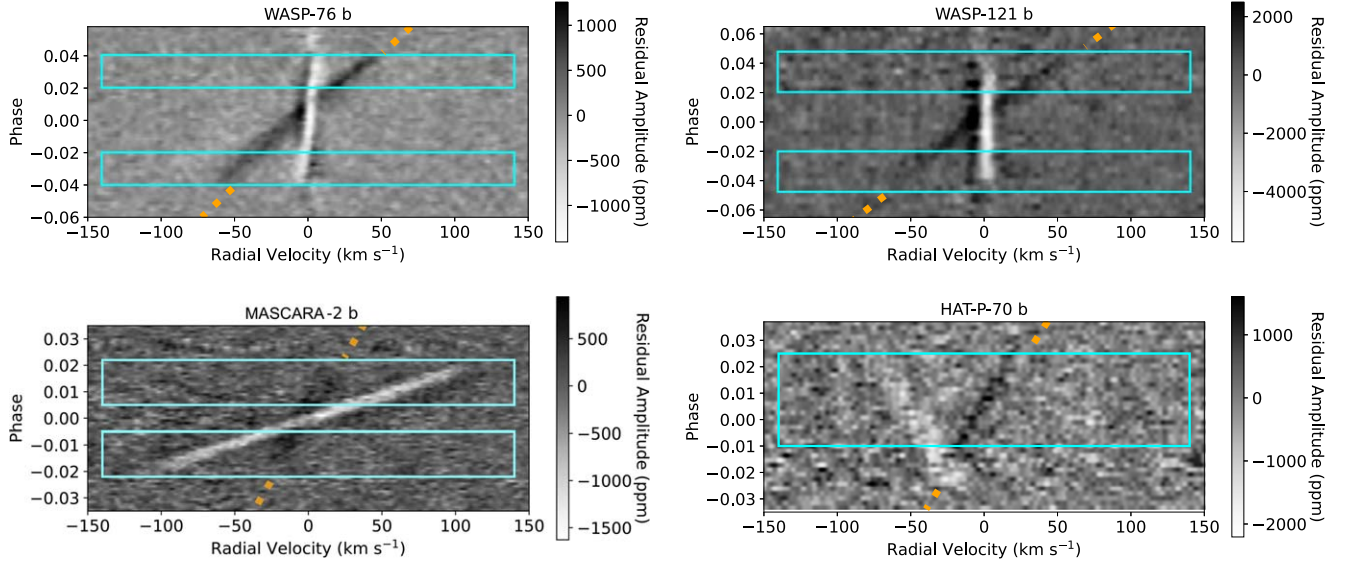

Figure 1. Combined Fe I cross correlation grids for all observed transits for WASP-76 b, MASCARA-2 b, WASP-121 b, and HAT-P-70 b. The dotted orange lines indicate the expected velocity of each exoplanet; positive (black) residuals along the orange dotted lines clearly show the detection of Fe I in each exoplanet with a signal-to-noise ratio >8 in every case. The cyan boxes indicate the regions that we used for the retrievals, chosen to avoid any spectra where the RM and CLV effects directly overlapped with the exoplanet’s spectrum.

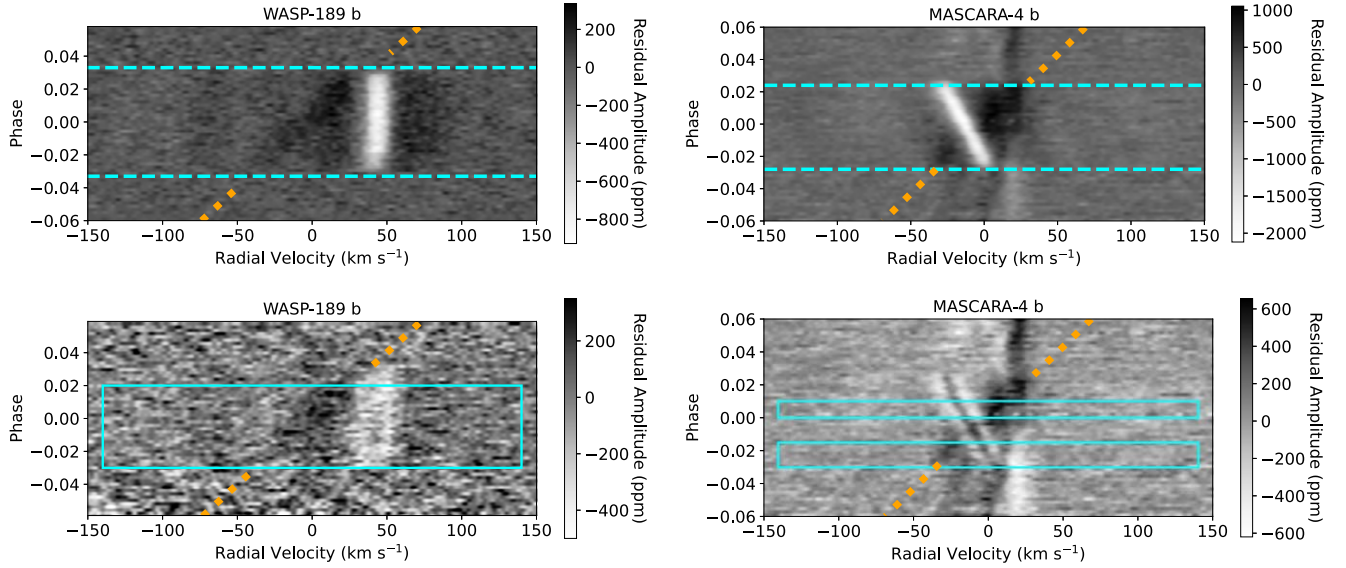

Figure 2. Similar cross correlation functions as Figure 1 but for MASCARA-4 b and WASP-189 b, which required a correction for Rossiter–McLaughlin (RM) effect and center-to-limb variations (CLV). The top panels show the uncorrected versions, while in the bottom panels our RM and CLV corrections have been applied. In both planets, significant residuals still remain after our corrections, but the amplitude of the stellar contamination is significantly reduced, and the planet’s signal can be more clearly extracted. Our retrievals using the corrected data converge to the planet’s known velocity, ensuring that the signal and molecules constrained are due to the planet. MASCARA-4 b also shows clear contamination due to stellar pulsations (residuals moving from black to white in the vertical direction near 20 km s^{-1}). We do not use spectra in the region where the residuals due to stellar pulsations are the most contaminated ($\phi = 0.01\text{--}0.03$).

Finally, we subtracted these synthetic RM and CLV model spectra from the data to produce the cleaned spectra. The cleaned cross-correlation functions (CCFs) are shown in Figure 2. As noted in previous works, this method does not remove all contamination from the RM and CLV effects (e.g., Casasayas-Barris et al. 2022; Zhang et al. 2022), but does noticeably improve the contamination. Even using the corrections, the regions where the RM effect directly overlaps with the planet’s signal is still highly contaminated, and so we still limit the phase ranges used for our retrievals to avoid the direct overlap (see Table 5). We found that the retrievals performed on the cleaned data converged to the planet’s known velocity

(K_p) for both cases, while the retrievals performed on the uncleaned data often converged to K_p values significantly different than the known values due to the RM and CLV residuals.

In Figure 2, MASCARA-4 b also shows residuals due to stellar pulsations, which were found to be similar across the two nights of observations. Zhang et al. (2022) assumed that the stellar pulsations remained constant in radial velocity with time, and so removed them by fitting Gaussians to the out-of-transit CCFs. The retrieval setup does not allow for fitting the residuals after cross correlation. We choose to instead omit the phase range that is most contaminated by stellar residuals

Table 2
Elemental Atmospheric Abundance Constraints (Given in Log(Volume Mixing Ratio)) and Their 1σ Errors for the Planets in Our Survey

Species	WASP-76 b	MASCARA-4 b	MASCARA-2 b	WASP-121 b	HAT-P-70 b	WASP-189 b
Fe	$-4.24^{+0.26}_{-0.24}$	$-4.68^{+0.2}_{-0.22}$	$-4.9^{+0.34}_{-0.27}$	$-4.49^{+0.44}_{-0.36}$	$-4.79^{+0.46}_{-0.44}$	$-4.94^{+0.24}_{-0.26}$

^a Ti value is the sum of the constraints for atomic Ti, and molecular TiO and TiH.

($\phi = 0.01-0.03$). Even with this limited range of phases, the retrievals quickly converge on the planet's known velocity, and so we are confident of our detections. We do note that the width of the CCFs (parameterized by δV_{wind}) is likely biased due to the pulsations. Furthermore, as the stellar pulsations affect all species, we expect the ratio of abundances (i.e., Mg/Fe, etc.) to be more reliable than that of absolute abundances for the case of MASCARA-4 b.

The cleaned spectra in the specified phase ranges were compared to the models in our retrieval framework. Following Gandhi et al. (2022), we convolved the models to the instrumental resolution and shifted them in velocity at each phase given their ΔK_p and ΔV_{sys} , which are free parameters in the retrieval. The model spectra are also scaled for limb darkening at each phase using the quadratic limb-darkening coefficients for each system. Finally, the spectra are rotationally broadened, and a high-pass filter is applied to the model to reproduce the steps in the data analysis.

The processed model and cleaned spectra are compared using a cross correlation to log-likelihood map (Brogi & Line 2019). The log-likelihood value for a given model compared against the data is computed with

$$\log L = -\frac{N}{2} \log(s_f^2 + s_g^2 - 2R), \quad (1)$$

where

$$s_f^2 = \frac{1}{N} \sum_{n=0}^N f^2(n); \quad (2)$$

$$s_g^2 = \frac{1}{N} \sum_{n=0}^N g^2(n-s); \quad (3)$$

$$R = \frac{1}{N} \sum_{n=0}^N f(n)g(n-s). \quad (4)$$

Here, f and g are the data and model respectively for a model with N spectral points, and s represents the wavelength offset. The overall value of the log-likelihood is the sum over all orders and phases. For planets where multiple transits were observed, the log-likelihoods of each transit were added to obtain the overall value. Our Bayesian analysis is performed with the nested sampling algorithm MultiNest (Feroz & Hobson 2008; Feroz et al. 2009; Buchner et al. 2014).

3. Results and Discussion

In this section, we discuss the results from our retrieved abundances and wind profiles for each planet and compare their constraints. We first explore the chemical constraints for the eleven species for each of the six planets in our survey, followed by a discussion of relative abundance constraints with high-resolution spectroscopy. We then discuss the HyDRA-2D retrievals performed on WASP-76 b and WASP-121 b, and the abundance variation of each species in the different regions of the terminator. Finally, we compare and contrast the wind profiles we obtain across the sample and discuss the mass constraints for MASCARA-2 b and HAT-P-70 b.

3.1. Chemical Abundances

We performed spatially homogeneous retrievals for the six planets in our survey, WASP-76 b, MASCARA-4 b, MASCARA-2 b, WASP-121 b, HAT-P-70 b, and WASP-189 b. We retrieve the volume mixing ratios of eleven species, Fe, Mg, Ni, Cr, Mn, V, Ca, Ti, TiO, TiH, and Na. These species were chosen as they are expected to be the most prominent in the optical and have often been detected in the atmospheres of UHJs (e.g., Merritt et al. 2021; Kesseli et al. 2022). Figure 3 and Table 2 show the abundance constraints for each species in each of the planets, with the overall Ti value as the sum of the constraints from atomic Ti, TiO, and TiH. We note that the abundances for each species correspond to the photospheric constraints at the terminator of these planets. The majority of species shows clear abundance constraints, with 2σ upper limits for the species that did not show any peak in the posterior distribution. From these, we can see that Fe is the most clearly constrained species, in line with expectations given its high abundance and opacity. Planets such as WASP-76 b and MASCARA-4 b show the tightest constraints given their multiple nights of high signal-to-noise observations.

To compare our retrieved abundances, we modeled the chemical equilibrium abundances of the species in our survey with FastChem (Stock et al. 2018). This chemical equilibrium code assumes that the chemical reaction rates are directly proportional to the concentrations of all reactants, also known as the law of mass action. By minimizing the Gibbs free energy of the closed atmosphere system, the abundances of various molecules, atoms, and ions are calculated at a given pressure and temperature in gas-phase. These models account for the ionization of species as well as the formation and interaction of molecules in the atmosphere, and the chemical element

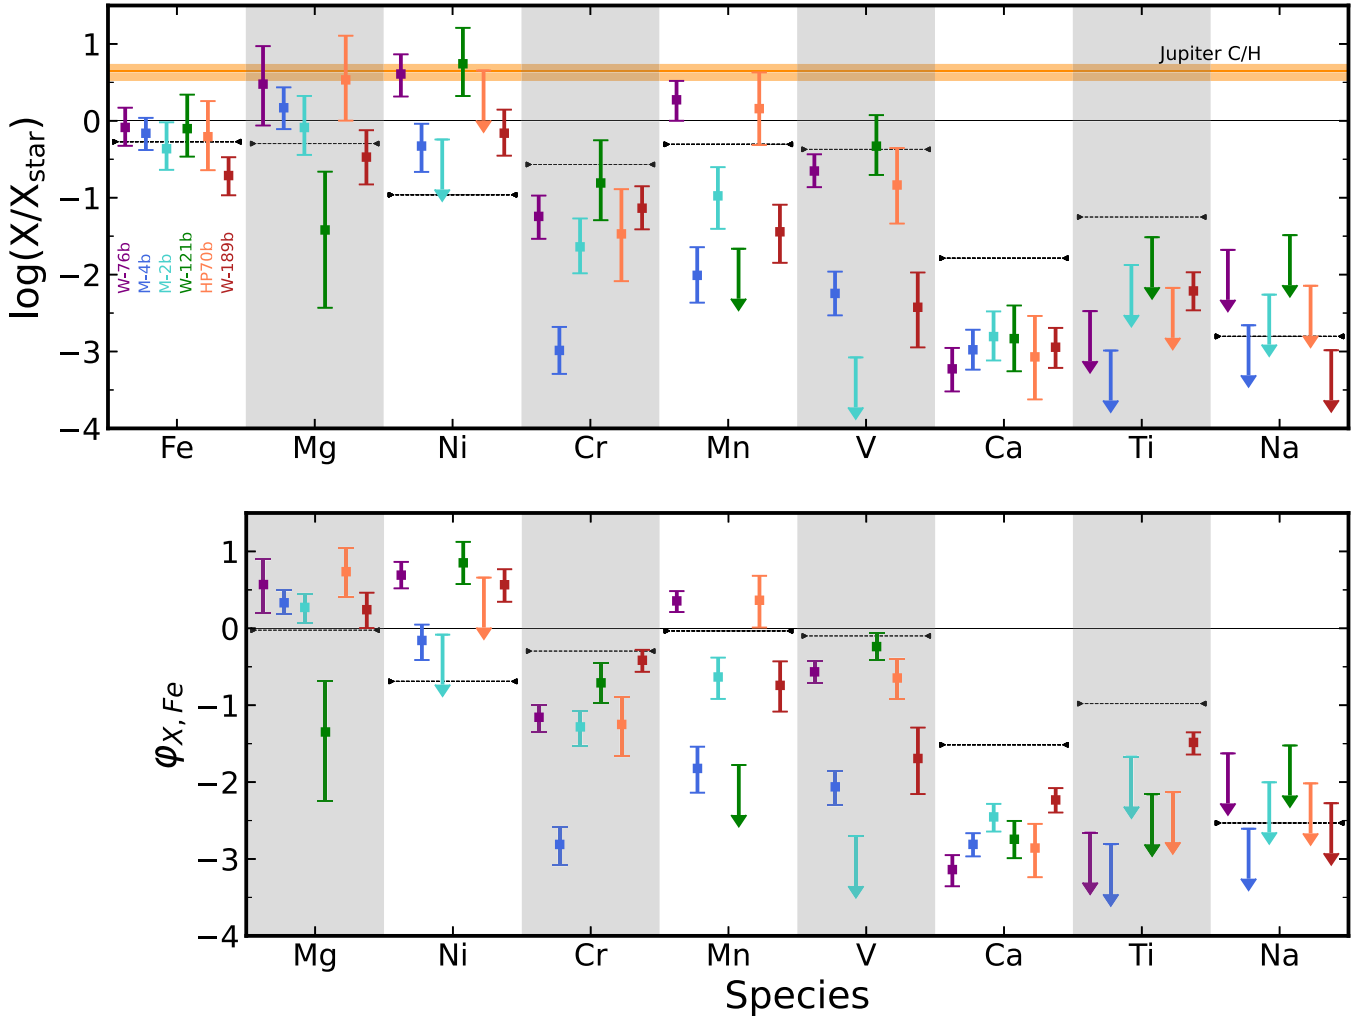

Figure 3. Top panel: volume mixing ratios and 1σ errors of each species relative to the stellar abundance for the planets in our survey, ordered by planetary equilibrium temperature. Bottom panel: values of $\varphi_{X,Fe}$ and 1σ errors for each species, defined as $\varphi_{X,Fe} = \log(X/Fe) - \log(X_{\odot}/Fe_{\odot})$, where X and Fe refer to the each species’ volume mixing ratios, and X_{\odot} and Fe_{\odot} refer to their solar abundance (see Section 3.3). Where no significant constraints were retrieved, we show the 2σ upper limit. Note that the Ti value is the sum of the constraints for atomic Ti, and molecular TiO and TiH. The dashed lines for each species indicate the expected abundance in chemical equilibrium at 3000 K and 0.1 mbar pressure (see Figure 4).

composition assumes solar abundances from Asplund et al. (2009). The abundances for each species are shown in Figure 4 as a function of pressure and temperature. We show the expected volume mixing ratio as well as the ratio of each of species to the total atom content, X_{tot} , of the atmosphere. Typically, high-resolution ground-based observations in the optical probe pressures near ~ 0.1 mbar (e.g., Maguire et al. 2023).

The chemical equilibrium models show that, as the temperature increases or the pressure decreases, the abundance of each species decreases due to ionization. Hence, we expect lower abundances of the neutral species as the temperature increases or as we probe higher up in the atmosphere. For species such as Fe and Mg, the overall ionization is low until we get to very high temperatures ($\gtrsim 3500$ K), but for others such as Ca, Ti, and Na, the abundance drops significantly at temperatures $\gtrsim 2700$ K and with decreasing pressure. For Ti, the dominant carrier of the atom is expected to be molecular TiO up to ~ 2500 K, after which point atomic Ti becomes stronger as the TiO dissociates, before that too depletes at higher temperatures as the neutral Ti ionizes.

3.1.1. Fe

We compared the Fe abundance of each planet relative to their host star’s metallicity, shown in Table 1. The constrained abundances of Fe for all of the planets are broadly consistent with the stellar value. This may indicate that these planets may have formed under similar conditions. Only WASP-189 b showed an Fe constraint with the 1σ error below the stellar Fe/H value, by ~ 0.7 dex. The chemical equilibrium models in Figure 4 show that the majority of the iron remains as neutral Fe for typical photospheric conditions unless the temperature becomes very high ($\gtrsim 3500$ K). As WASP-189 b is the hottest planet in our sample (see Figure 11), the lower value of Fe may be due to a significant amount of Fe being ionized. Alternatively, the lower Fe abundance could hint at a mass-metallicity trend as WASP-189 b is the most massive planet in our sample that has a known mass determination (see Table 1).

Figure 5 shows the mass–metallicity relation from the Fe/H for each of the planets in our survey. We determine the masses of MASCARA-2 b and HAT-P-70 b from the median value of $\log(g)$ retrieved for each (see Section 3.6). We see a weak trend of decreasing abundance with mass in line with the solar

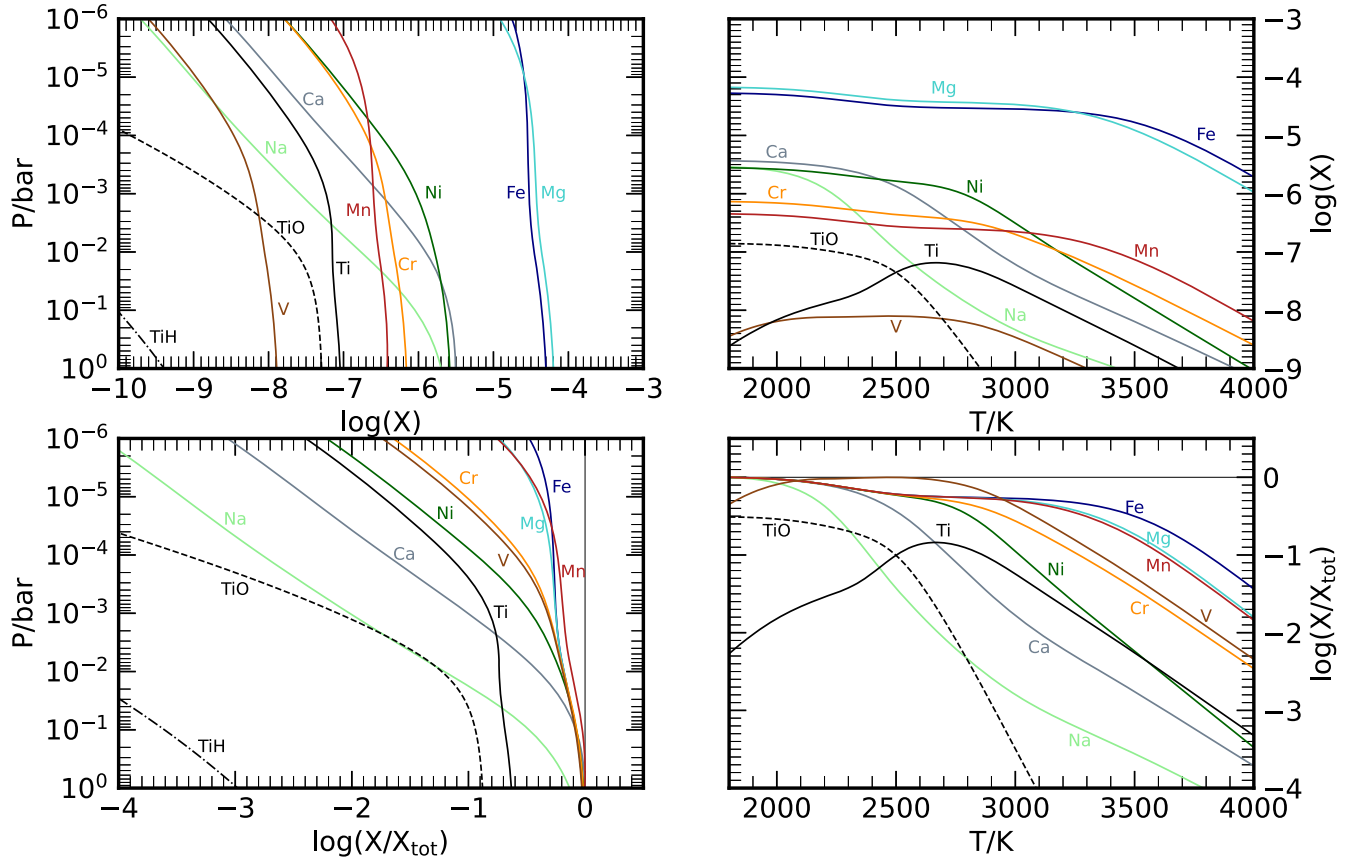

Figure 4. Chemical equilibrium abundances (in log(volume mixing ratio)) of each species at solar elemental abundance (Asplund et al. 2009). The top left panel shows the variation of the volume mixing ratio of each species with the pressure at a fixed isothermal temperature of 3000 K. The top right panel shows the variation of volume mixing ratio with the temperature at a fixed isobaric pressure of 0.1 mbar. The bottom panels for each side show the corresponding fraction of each species to the total atom content in the atmosphere, X_{tot} .

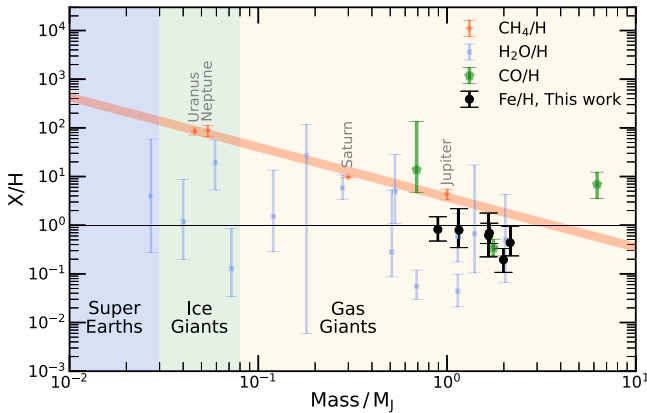

Figure 5. Mass-metallicity relation for known exoplanets and the solar system, corrected for the stellar metallicity of each system. The Fe constraint for each planet from this work is shown in black. The orange region indicates the solar system trend. We also show the $\text{H}_2\text{O}/\text{H}$ (blue) and CO/H (green) constraints for a range of exoplanets obtained with low-resolution and high-resolution observations respectively (Welbanks et al. 2019; Guillot et al. 2022).

system trend in C/H , but significant trends are difficult to ascertain given the limited mass range of these planets. Our findings are consistent with recent work from low-resolution retrievals, which showed at or near stellar abundances of alkali metals in hot Jupiters (e.g., Welbanks et al. 2019). On the other hand, recent high-resolution dayside observations of MAS-CARA-2 b and other ultrahot Jupiters have shown evidence for

superstellar abundances (Cont et al. 2022; Kasper et al. 2023), indicating that there may be some variation in abundances of Fe in UHJs. Neutral Fe remains gaseous down to temperatures of ~ 1350 K at 0.1 mbar (see Table 3), does not strongly ionize until high temperatures (see Figure 4), and is the dominant carrier of iron for these UHJs (Visscher et al. 2010). Therefore, neutral Fe is likely to be a good measure of the bulk Fe composition of such targets. However, this also holds true for other species such as neutral Mg, Cr, or Mn, which are also relatively stable and the dominant carrier of the atom. Hence, using their abundance as a proxy for atmospheric metallicity for the planets in our survey could potentially result in differing conclusions (see below), and highlights the difficulty of using the abundance of a single species to probe bulk metallicity.

The atmospheric abundance of refractory species such as Fe is a particularly important quantity as it is an indicator of the rock composition accreted during the planet’s formation (Lothringer et al. 2021). Chachan et al. (2023) further demonstrate how measuring the abundances of refractory species, specifically Fe, can break degeneracies that exist when trying to determine the formation location of an exoplanet when using only volatile species, such as C- and O-rich species. In the future, our results of measured refractory abundances can be combined with abundances of volatiles from near-infrared observations, to constrain how the population of ultrahot Jupiters formed and evolved, as was recently done with dayside spectra (Kasper et al. 2023).

3.1.2. Mg, Ni, Cr, and Mn

The abundances of Mg, Ni, Cr, and Mn show weaker constraints and greater variation than Fe. The Mg constraints have a wider uncertainty given the relatively few spectral lines in the range of our observations, but these agree well with the results for Fe. Our Ni abundance across the sample shows a trend of superstellar values, but Cr indicates more substellar abundances, particularly for MASCARA-4 b. In some of our retrievals, we constrain very low abundances ($\log(\text{Volume Mixing Ratio}) < -9$) for Cr owing to their strong optical opacity and the high-precision observations. Pelletier et al. (2023) find a similar trend in their retrievals of WASP-76 b and suggest that an increased Ni abundance could be due to an impact during planet formation. However, neither constraints for Ni or Cr are as significant as Fe given the generally weaker absorption of these species, making precise abundance constraints and hence interpretations more difficult. Ni has a higher ionization fraction than Fe, Mg, Cr, or Mn (see Figure 4), and its higher retrieved abundances may also be an indicator of vertical mixing driving more neutral Ni toward the photosphere at higher altitudes. The Mn abundance also shows variation across our sample, with WASP-76 b and HAT-P-70 b indicating superstellar abundances but with the other planets indicating substellar values. Hence, further observations of the terminator of UHJs are required to explore these variations in abundances further.

We note that we are able to constrain Ni and Mn in the atmosphere of MASCARA-4 b, but Zhang et al. (2022) were not able to clearly pick this up in cross correlation. The retrieval is able to explore a wide range of chemical abundances, temperature profiles, and opacity decks, which increases the parameter space probed, which may result in better constraints. This is particularly important for species such as Mn, which was constrained to be ~ 2 orders of magnitude lower than its expected value. Furthermore, our retrieval fits for all species simultaneously, meaning that masking of spectral features from Ni and Mn by other stronger species (e.g., Fe) is accounted for. The observations of MASCARA-4 had strong RM+CLV, which we did model, and we ensured that we used phases that avoided the stellar residuals, but we caution that our constraint for this planet may be affected by some uncorrected stellar residuals. Zhang et al. (2022) were also able to detect Na, but our retrievals showed only a weak peak with no clear constraint (see Section 3.1.5), indicating that these two methodologies may have slight advantages and disadvantages for weak chemical signatures depending on the species being probed.

3.1.3. V

The V abundance for the planets in our survey also shows more variation, with WASP-76 b, WASP-121 b, and HAT-P-70 b showing abundances consistent with the stellar values, but MASCARA-4 b, MASCARA-2 b, and WASP-189 b showing significantly lower values or upper limits. This may potentially be due to the formation of VO, which depletes the atmosphere of neutral V. We do not include VO as part of our analyses given the lack of reliable high-resolution line lists available (de Regt et al. 2022). VO possesses a strong optical opacity and is also capable of causing thermal inversions in ultrahot Jupiters (e.g., Hubeny et al. 2003; Fortney et al. 2008; Gandhi & Madhusudhan 2019). On the other hand, the three planets with

the lowest V abundances also possess the strongest RM and CLV, which may be interfering with the V signal in the observations. Cont et al. (2022) suggest depleted V abundances for the UHJ WASP-33 b in emission compared with other species, showing that there may be some variation in inferred V abundances in UHJs.

3.1.4. Ca and Ti

The chemical equilibrium models show that the neutral Ca and Ti are expected to be reduced by $\sim 1-2$ orders of magnitude at a temperature of 3000 K and 0.1 mbar pressure (dashed line in Figure 3). This brings us to a much closer agreement to the retrieved abundances for these species. However, there are still some differences, with Ca and Ti constrained to be even lower than what the chemical equilibrium models predict. This may indicate that the temperature is higher, as this will act to further ionize the Ca and Ti and reduce the retrieved abundances. The temperature profile constraints do indicate that the median temperatures are higher than 3000 K for many of these planets (see Figure 11), but our retrieved abundances do not show a strong dependence with the retrieved temperature profiles. In fact, the Ca abundance in WASP-76 b, the coolest planet in our survey, is the lowest of any of the planets when we account for the host star metallicity (see Figure 3).

A potential explanation for the low abundances of gaseous Ca and Ti-bearing species is the formation of CaTiO_3 clouds on the nightside, depleting the Ca and Ti in the atmosphere due to rain-out. These clouds form at temperatures of ~ 1600 K at 0.1 mbar (see Table 3), and the nightsides of UHJs have been shown to be cool enough for such clouds to precipitate (Mikal-Evans et al. 2022). As CaTiO_3 has the hottest condensation temperatures for the species used in our work, Ca and Ti are the most likely to be depleted due to rain-out on the nightside. Hence, Ti-bearing species may be sequestered deep in the interior of the planet through cold-trapping (e.g., Spiegel et al. 2009). Recent work has also shown no evidence for Ti or TiO in WASP-121 b (Hoeijmakers et al. 2022; Maguire et al. 2023), or TiO in MASCARA-2 b (Johnson et al. 2023).

Across our sample, we are only able to constrain Ti-bearing species (both Ti and TiO) in WASP-189 b, as found by Prinoth et al. (2022). This is the hottest exoplanet in our sample with temperature constraints ~ 3900 K (see Figure 11), and hence least susceptible to condensation of Ti-rich species. The lower equilibrium abundances of neutral species such as Fe at these high temperatures may also reduce the shielding of Ti and TiO spectral features in addition to any effect clouds and/or quenching may have. TiO is of particular interest given that it has strong optical opacity and can cause thermal inversions in the photosphere (e.g., Hubeny et al. 2003; Fortney et al. 2008; Piette et al. 2020).

Another possibility is vertical chemical gradients in the atmosphere, which artificially reduce the constrained abundance. The chemical equilibrium models show that Ca, Na, and Ti are expected to have some of the strongest decreases in their abundance with atmospheric height, but our retrieval is not able to capture this given that we assume vertically homogeneous chemistry. Hence, the cores of spectral lines, which are generated at lower pressures, will be weaker than expected given the strong ionization of neutral species in the upper atmosphere, and will therefore drive the retrieved abundances to lower values. In addition, other species containing Ca may form in the atmosphere and deplete the atmosphere of neutral

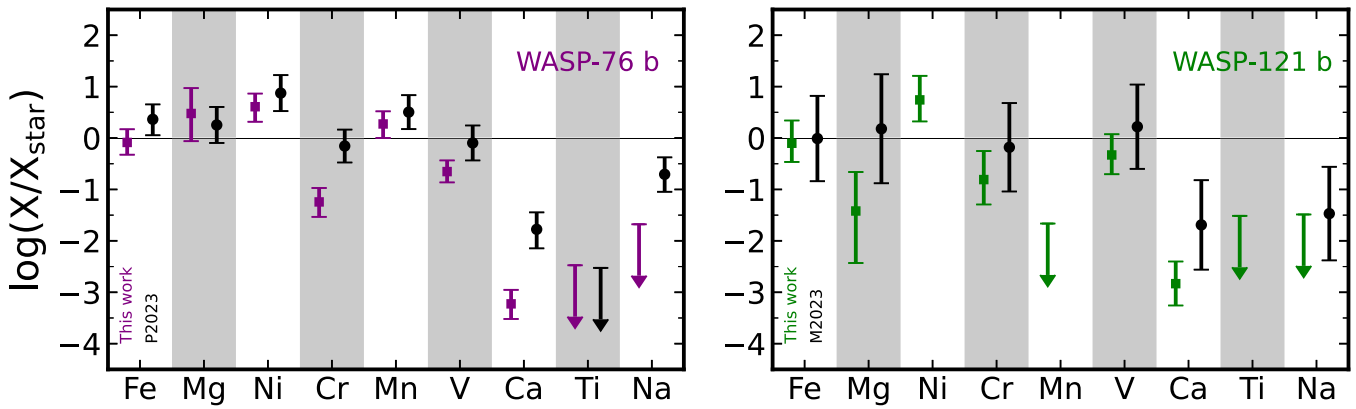

Figure 6. Comparison of our retrieved abundances for each species with Pelletier et al. (2023) for WASP-76 b in the left panel and Maguire et al. (2023) for WASP-121 b in the right panel.

gaseous atoms. Molecules such as CaO have also been shown to be capable of causing stratospheres in the atmospheres of UHJs (Gandhi & Madhusudhan 2019), but are likely to make up a small fraction of the overall Ca budget in equilibrium. Determination of the Ca+ abundance will provide a key indicator to the overall ionization of neutral Ca and the total Ca content of the atmosphere, as many of these planets have shown very strong Ca+ absorption (Merritt et al. 2021; Kesseli et al. 2022; Zhang et al. 2022; Pelletier et al. 2023). However, including this into retrievals may be challenging as they probe the exosphere (Maguire et al. 2023).

3.1.5. Na

Neutral Na is expected to be substantially ionized at the conditions typical for ultrahot Jupiter photospheres, with the equilibrium models indicating depletion by almost 3 orders of magnitude at 3000 K and 0.1 mbar (see Figure 4). Given this lower abundance and the relatively few prominent spectral lines, our retrievals are unable to conclusively constrain Na for any of the planets, but the upper limits on the retrieved abundances are consistent with the equilibrium model predictions, with 2σ upper limits around $\log(\text{Na}) \sim -8$ (see Table 2). We did obtain tentative peaks for Na in WASP-121 b and MASCARA-4 b, hinting at a detection, but in both cases, there was a long tail in the abundance distribution that extended to the edge of our prior, and so we conservatively do not report these as confident detections. Other works have been able to constrain Na through other observations (see Section 3.2). However, given its relatively few spectral lines, direct detection of the spectral features from the Na $\sim 0.589 \mu\text{m}$ D lines have proved the most effective to detect Na in these planets (e.g., Casasayas-Barris et al. 2019; Seidel et al. 2019; Borsa et al. 2021; Langeveld et al. 2022; Zhang et al. 2022). Furthermore, the Na feature had a velocity shift relative to other species such as Fe for WASP-76 b (Kesseli et al. 2022), as well as a significant velocity offset from the known orbital solution for WASP-121 b (Seidel et al. 2023). This may also reduce our constraints given that the retrieval assumes no velocity shifts between species. We note that the strong opacity of the Na D lines may also result in the absorption features occurring in the nonhydrostatic regions of the atmospheres at very low pressures (Hoeijmakers et al. 2020b; Gebek & Oza 2020), thereby making accurate inferences of Na abundances more difficult.

3.2. Comparison with Previous Works

We compared our results to previous retrievals of the terminator of WASP-76 b and WASP-121 b. These used MAROON-X/Gemini-North observations by Pelletier et al. (2023) for WASP-76 b and ESPRESSO/VLT observations by Maguire et al. (2023) for WASP-121 b. The comparison of the retrieved volume mixing ratios are shown in Figure 6. We find excellent agreement with both studies, but Pelletier et al. (2023) did constrain higher abundances for Cr and Ca in WASP-76 b compared with our values. Their work constrained both neutral Ca and ionized Ca+ and showed that the Ca+ dominates over the neutral Ca, indicating that the calcium in the atmosphere is almost completely ionized. They were also able to constrain Na, with an abundance slightly above that of our upper bound. For WASP-121 b, Maguire et al. (2023) retrieved upper limits to Ti similar to ours, but did constrain Na at abundances similar to but slightly above our upper bounds. Furthermore, Gibson et al. (2022) constrained Fe, Mg, Cr, and V in WASP-121 b with UVES/VLT observations, which are also in good agreement with our abundance constraints. We note that for these studies and our retrievals the relative abundances are more robust (see below). However, given the differences in data sets, analyses, and atmospheric modeling, the consistency of these results is encouraging, and a verification of the statistical and modeling frameworks used for high-resolution retrievals.

3.3. Constraining Relative Abundances with High-resolution Spectroscopy

Figure 7 shows the posterior distribution for WASP-189 b, where we clearly constrain the abundances for nine atomic and molecular species and the pressure level of the opacity deck. The posterior shows that the abundance constraints are negatively correlated with the location of the opacity deck, as found previously for Fe for WASP-76 b (Gandhi et al. 2022). This is because HRS is more sensitive to the relative strengths of the spectral lines over the continuum (i.e., the opacity deck), rather than the absolute level. Species with strong opacity, such as Fe, TiO, and Cr, were the most strongly correlated with the opacity deck given their significant number of spectral lines. Therefore, this leads to abundances between species being positively correlated with each other. For some species such as Cr, the trend of increasing abundances with increasing Fe is particularly strong (see Table 4). This indicates that relative

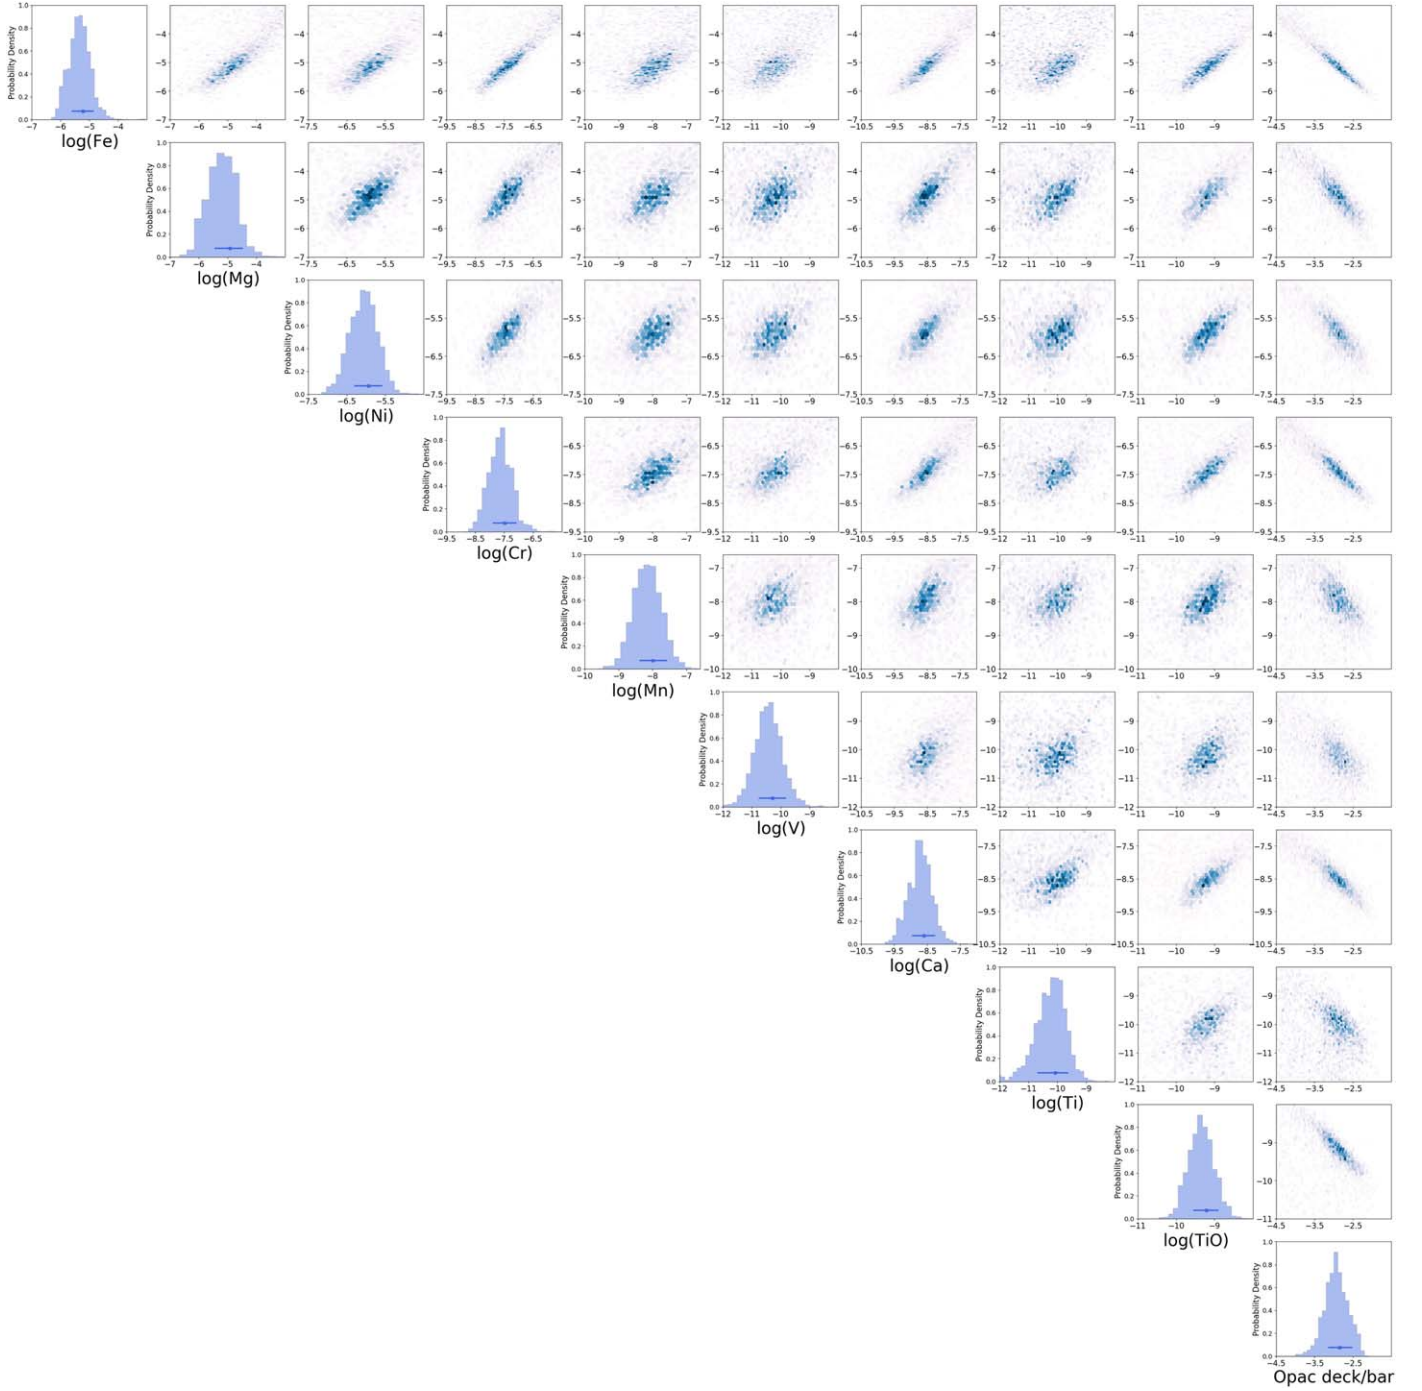

Figure 7. Posterior distribution of the volume mixing ratios of Fe, Mg, Ni, Cr, Mn, V, Ca, Ti, TiO and the opacity deck for the HyDRA-H retrieval of WASP-189 b performed over the $\phi = -0.033 - +0.02$ range. These highlight the dependence of each parameter on the other (see Section 3.3).

abundance constraints with high-resolution spectroscopy are much more precise and robust, as found by previous works (e.g., Gibson et al. 2022; Maguire et al. 2023; Pelletier et al. 2023). Such relative abundances over the continuum are also common in low-resolution spectroscopy (e.g., Welbanks & Madhusudhan 2019), indicating this is a general feature of transmission spectroscopy.

It is instructive to define a new variable that allows us to clearly explore the relative abundances between species. We define $\varphi_{A,B}$ as

$$\varphi_{A,B} \equiv \log(X_A/X_B) - \log(X_{\text{star},A}/X_{\text{star},B}), \quad (5)$$

where X_A and X_B are the atmospheric volume mixing ratios, and $X_{\text{star},A}$ and $X_{\text{star},B}$ are the stellar volume mixing ratios of species (A) and (B) respectively. This allows us to determine the relative enhancement of one species over another with respect to the stellar values. Note that this is similar to definition of the stellar metallicity,

$$[\text{Fe}/\text{H}] \equiv \log(X_{\text{star,Fe}}/X_{\text{star,H}}) - \log(X_{\odot,\text{Fe}}/X_{\odot,\text{H}}), \quad (6)$$

where $X_{\odot,\text{Fe}}$ and $X_{\odot,\text{H}}$ refer to the solar abundances of Fe and H. For our work, we use φ in order to distinguish the planetary abundances and avoid confusion with the stellar values. We

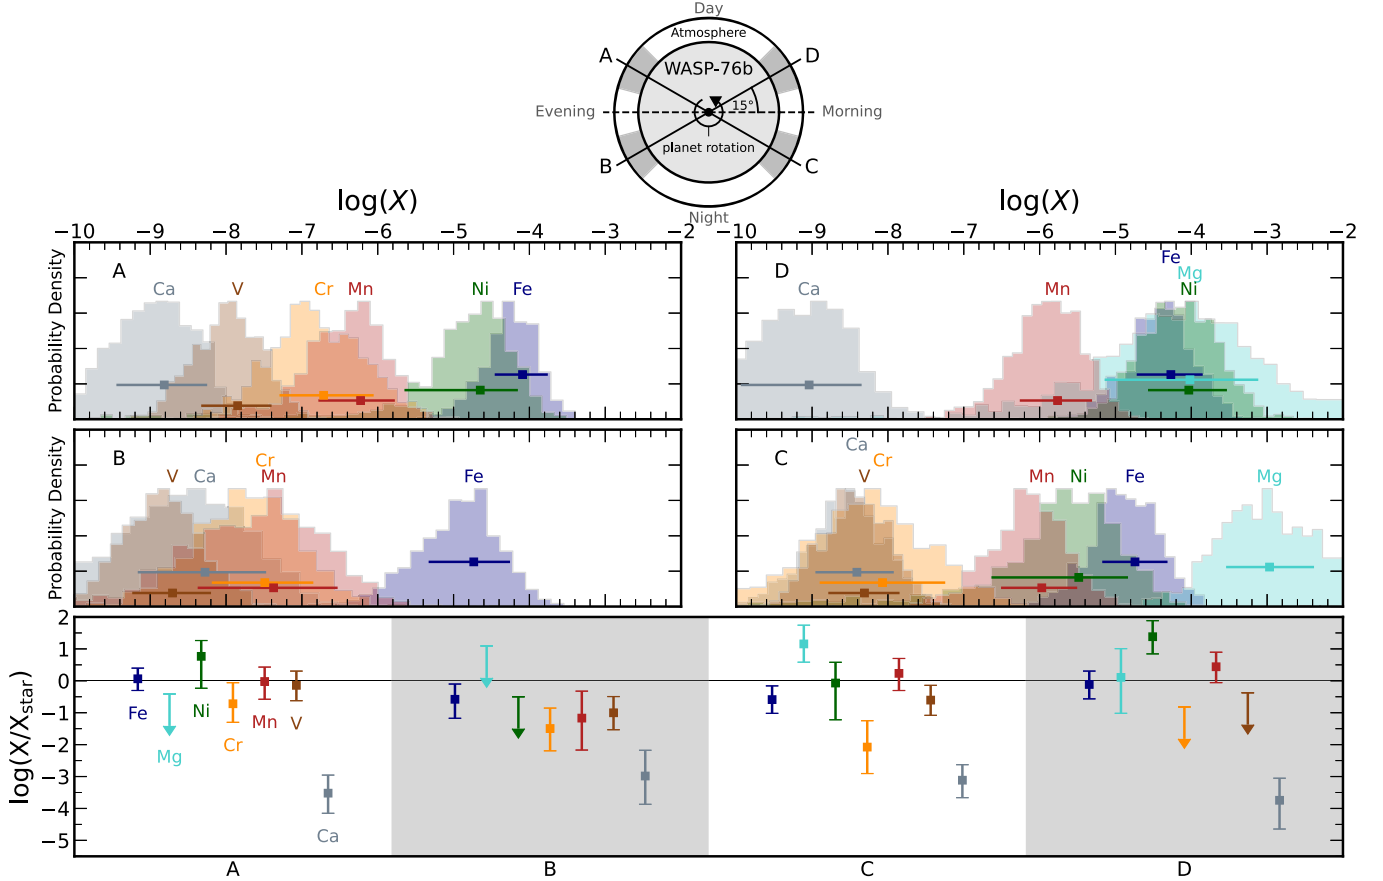

Figure 8. Atmospheric abundance constraints for each species from our HyDRA-2D retrieval of WASP-76 b. The schematic at the top of the figure indicates the regions of the atmosphere that are being probed, with (A) and (D) being irradiated by the incident stellar flux. The middle 4 panels show the posterior distributions for each species in each of the regions of the atmosphere, along with their median and $\pm 1\sigma$ error bars. For clarity we only show those species with a clear posterior peak from the retrieval. The bottom panel shows the ratio of the abundance of each species to the stellar value, with 2σ upper limits for those species without a clear constraint.

often scale the stellar $[\text{Fe}/\text{H}]$ value for the abundances of the other species in the star. This reduces $\varphi_{A,B}$ to

$$\varphi_{A,B} = \log(X_A/X_B) - \log(X_{\odot,A}/X_{\odot,B}). \quad (7)$$

We have now removed the dependence on the measured host star metallicity. As an example, a value of $\varphi_{A,B} = 2$ means that ratio of species (A) to species (B) is $100\times$ that of their solar abundance ratio.

Figure 3 (bottom panel) and Table 4 show the constraints on $\varphi_{X,\text{Fe}}$ for each of the species in the planets in our survey. The values show that almost every species has an improved error constraint for relative abundances over their absolute values (given in Table 2), and highlights the strength of HRS to constrain relative abundance ratios. This is an important insight and shows it may be more reliable to use such relative abundance ratios as observational tracers and/or parameters in retrievals. This also shows that abundance ratios such as the Fe/O or C/O ratios obtained through high-resolution infrared observations may be more reliable than absolute abundances, therefore allowing us to robustly explore formation scenarios (Öberg et al. 2011; Lothringer et al. 2021).

However, we note that relative abundances can also have biased estimates in their values, such as if any RM and/or CLV affect from the star is greater for one species over another. For each of our planets, we chose phase ranges that avoided the

stellar contamination to ensure unbiased estimates of the planetary signal, which were not influenced by the star or its atomic abundances. Furthermore, if species have velocity/wavelength shifts relative to one another this can also bias the retrieved ratios, as our retrieval assumes that the line positions of species do not have any relative shifts between one another. These shifts can arise due to species being probed at different altitudes, where the wind shear can alter the overall Doppler shifts of spectral signals. For UHJs it is expected that the strongest wind speeds occur at the lowest pressures (e.g., Wardenier et al. 2021), and hence the species with strong spectral lines probing these upper regions of the atmosphere will have more significant Doppler shifts.

3.4. Variation in the Terminator of WASP-76 b and WASP-121 b

Figures 8 and 9 show the constraints on seven atomic species in the terminator regions of WASP-76 b and WASP-121 b respectively using HyDRA-2D. We did not conclusively detect Ti, TiO, TiH, or Na in our spatially homogeneous and phase-combined retrievals for either planet (see Section 3.1), and thus they were not included in our HyDRA-2D retrievals for computational efficiency. Our results for both planets are generally consistent with the constraints described above, and most species show similar abundances in each region. This

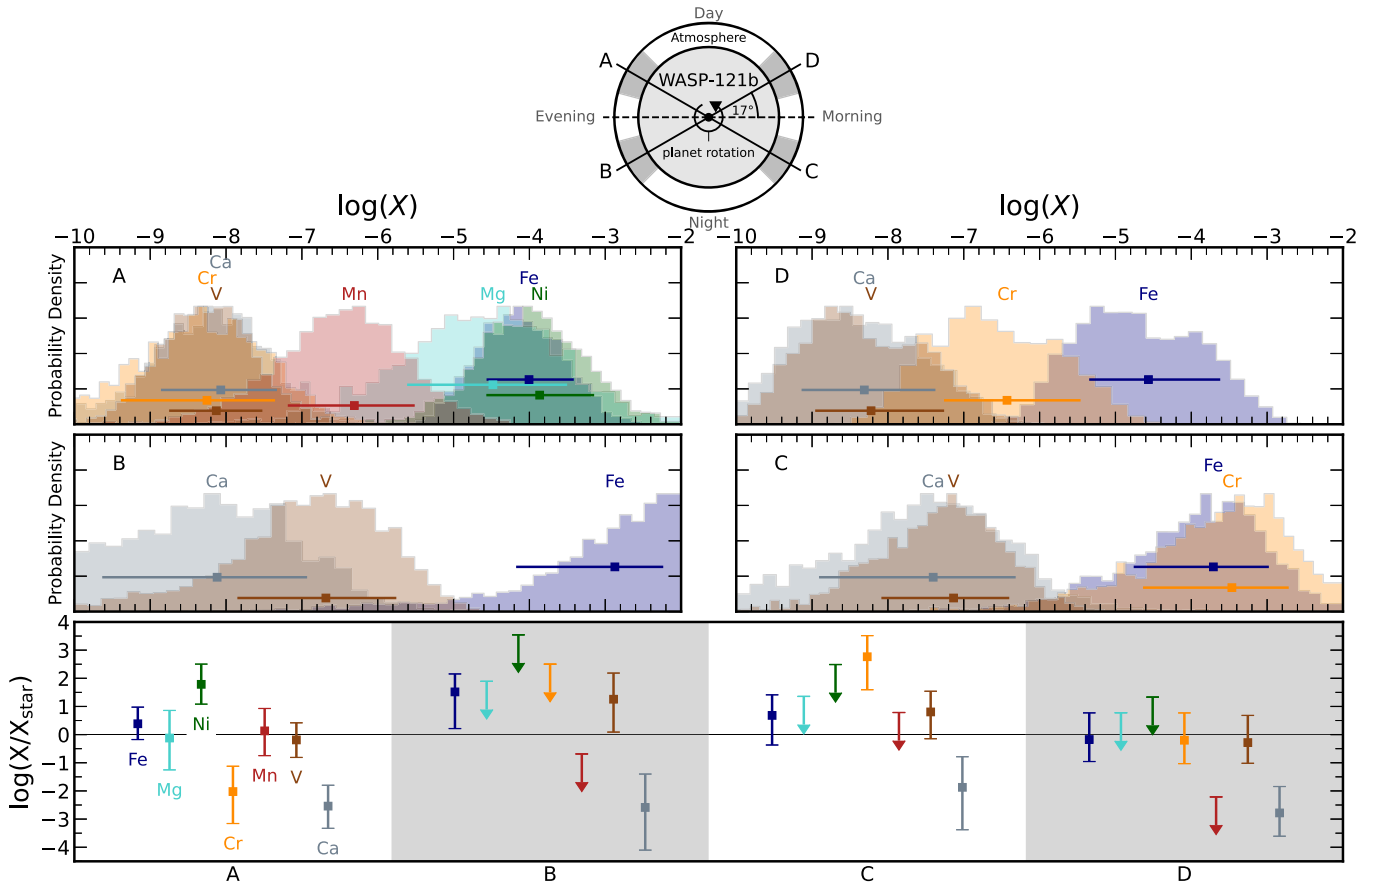

Figure 9. Atmospheric abundance constraints from our HyDRA-2D retrieval of WASP-121 b (see Figure 8 for details).

points to a terminator that is broadly homogeneous, with only some slight differences in the chemistry. Hence, other factors such as variation in the thermal profile between each region and winds in the upper atmosphere are likely to play a larger role in spectral differences, consistent with previous works in emission geometries (Beltz et al. 2021).

The retrievals show that all of the retrieved species show strong constraints in some regions of the atmosphere. In particular, Fe is well constrained in all 4 regions of the terminator for both of the planets, owing to its high abundance and prominent opacity in the optical wavelengths where the ESPRESSO observations probe. We generally find that the abundance is consistent with the stellar value. For WASP-76 b, we find that our abundance constraints for the nonirradiated regions (regions (B) and (C) in Figure 8) are the weakest with the lowest abundance. This is consistent with previous theoretical works suggesting rain-out of Fe on the nightside, clouds obscuring the morning and/or leading side terminator and/or thermal differences between the two sides leading to a lower and less-well-constrained abundance (Ehrenreich et al. 2020; Wardenier et al. 2021; Gandhi et al. 2022; Savel et al. 2022). On the other hand, we do not see such a difference between the different regions of the terminator for WASP-121 b, which may be due to its higher irradiation preventing significant rain-out and/or cloud formation. We note that the Fe abundance for WASP-121 b for region (B) is only a lower limit and is not fully bounded by our retrieval as the posterior extends toward the upper edge of the prior range. However, this is still consistent with the abundance in the other regions.

In addition to Fe, we constrain Mg, Ni, Cr, Mn, V, and Ca in both planets, but some species only show upper bounds on the abundance for some regions. For WASP-76 b, Mn shows significant peaks for all regions of the atmosphere, but the Cr and V abundance is only well constrained in regions (A), (B), and (C). On the other hand, Ni is only prominently detected in regions (A), (C), and (D), with the irradiated regions (A) and (D) showing the tightest constraints. One of the most difficult species to constrain on each side was Mg given its fewer spectral lines, and we only obtained clear detections for the morning and/or leading side of the terminator. Generally however, we find that the regions that only show upper limits are consistent with the values in the constrained regions for all species.

The abundance constraints for WASP-121 b in Figure 9 are generally weaker and show a wider uncertainty for each species due to the single night of observations used in our study. While Fe, Ca, and V show clear posterior peaks, the other species are not seen in all regions. One of the most intriguing constraints that we observe is for Mn, where we see a clear peak for the species in region (A) but were not able to clearly constrain it in our spatially homogeneous retrievals or in any other terminator region of the spatially resolved and phase-separated retrievals. This may point to some slight offsets in velocity in the Mn signal over the other species, potentially arising from differential wind speeds given that the spectral signals arise from slightly different altitudes for each species. On the other hand, if the Mn is only prominent on one side of the atmosphere, the spatially homogeneous retrieval may not be able to clearly constrain it given that it will have a stronger

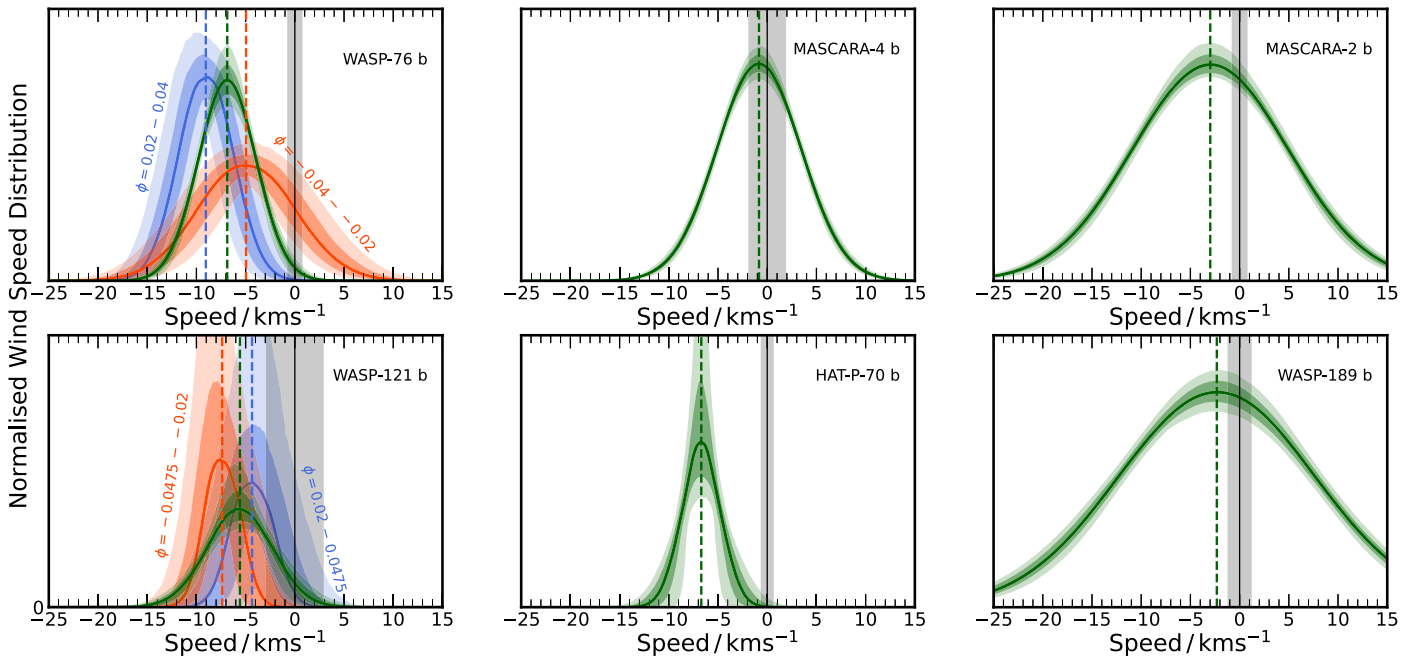

Figure 10. Normalized wind speed distribution in each exoplanet’s rest frame, derived from the ΔV_{sys} and δV_{wind} parameters. The shaded green regions show the 1σ and 2σ uncertainties on the distribution for the HyDRA-H retrievals (given in Table 5). We also show the constraints from the HyDRA-2D retrievals of WASP-76 b and WASP-121 b in orange (first part of transit) and blue (last part of transit). The dashed lines indicate the median ΔV_{sys} values. Negative values correspond to a net blueshift, as a result of a day-to-night wind. The gray shaded regions show the 3σ uncertainty on the known value of V_{sys} .

blueshift than that of the species that have more equal prominence across both halves of the terminator. In addition, the upper limit for Mn in region (D) appears to be inconsistent with the constrained abundance in region (A), further supporting this difference in Mn between the two sides. MnS clouds are expected to form at temperatures below ~ 1100 K (see Table 3), but this is not consistent with our temperature constraints of $\gtrsim 2000$ K for the terminator, or with the clear constraint obtained for Mn in WASP-76 b, the planet with the lowest equilibrium temperature in our survey. Hence, further observations of the terminator are needed to fully ascertain the variation of Mn in the terminator.

For some species, such as Cr, we find that a higher abundance and/or stronger constraint in region (A) results in weaker constraints in region (C) and vice versa. To separate regions (A) and (C) and regions (B) and (D), we split the terminator into two halves and retrieve separate chemical abundances for each side. However, abundance constraints for one side may influence the constraints for another, as regions (A) and (C) and regions (B) and (D) are retrieved simultaneously in the retrieval. Hence, any velocity shifts between species may be compensated by increasing the abundance for one side or the other. In addition, a higher abundance or stronger signal for a given species in one region may spread its spectral features out over the other region of the atmosphere. This is because the spectral lines are broadened and therefore may be partially blended together, thus resulting in a lower abundance and/or a wider uncertainty for the region with weaker absorption. This is similar to that seen for Fe in WASP-76 b, where the more dominant signal from region (A) increases the uncertainty in region (C) (Gandhi et al. 2022).

We find that the evening (or trailing) side for the last part of the transit (region (A)) generally has the strongest constraints on the abundances for each species. This is because this is the

region that is being irradiated and hence has the highest temperatures from our retrievals. The higher temperatures mean that the scale height of the atmosphere is increased, and thus these regions of the terminator are the dominant part of the signal. Any east–west meridional circulation patterns would also act to shift the dayside hotspot toward the eastern side of the planet and thus closest to region (A). Hence we expect this to be the region with the strongest absorption and therefore the most tightly constrained abundances.

3.5. Wind Speeds

Atmospheric winds have a strong influence on the high-resolution observations, through Doppler shift and broadening of lines in the observed spectra (e.g., Showman et al. 2013). For such planets, the dominant winds in the upper atmosphere are expected to be those that travel from the dayside of the atmosphere toward the night, and thus lead to an overall blueshift of the spectrum as material travels toward the observer (e.g., Miller-Ricci Kempton & Rauscher 2012; Flowers et al. 2019; Wardenier et al. 2021; Savel et al. 2022). The wind speeds are determined by the balance of day–night temperature contrasts and dissipation mechanisms such as hydrodynamic or magnetic drag (e.g., Gandhi & Jermyn 2020; Beltz et al. 2022). Figure 10 shows the constrained value of ΔV_{sys} , the proxy for the wind speed, and the spread in its velocity, δV_{wind} , assuming a uniform day–night wind. The wind broadening kernel is assumed to be a Gaussian profile and is separate from the Doppler shift due to rotation, which is applied as rigid body rotation assuming a tidally locked planet (e.g., Showman & Guillot 2002). As we account for this planetary rotation, the wind speed distribution in Figure 10 is driven by the winds and/or other broadening effects, and therefore can be compared across planets regardless of their rotation.

The retrieved values of ΔV_{sys} are dependent on the precision of the stellar velocity (V_{sys}), the time of mid transit (T_c), and the orbital period (P). All of the planets are extremely well-studied due to the fact that they orbit bright stars and have short orbital periods, leading to many observed transits over years of baseline. The uncertainties in V_{sys} for each star are $\lesssim 0.15 \text{ km s}^{-1}$ (see Table 1). We propagate the uncertainty in T_c and P for each system and find that for each case the change in the measured ΔV_{sys} value is less than 0.3 km s^{-1} . We note that these are fitting errors and do not account for the overall systematic uncertainty and may potentially be larger. However, because the retrieved ΔK_p and ΔV_{sys} values are correlated (see, e.g., Gandhi et al. 2022) and the K_p values have larger uncertainties of $1\text{--}6 \text{ km s}^{-1}$, this is actually the largest source of uncertainty on ΔV_{sys} . Even with the larger uncertainties on K_p , we still find the total propagated uncertainty in ΔV_{sys} is less than 1 km s^{-1} in every case, and cannot explain the overall net blueshifts we observe in the planet atmospheres.

All retrievals for all of the planets have a net blueshift (i.e., a negative velocity) of the planetary signal relative to the known value of the systemic velocity, which we interpret as evidence of a day–night wind. In addition, the median value of the offset is more than the overall 3σ propagated uncertainty in the measured value of V_{sys} for every planet except MASCARA-4 b (see Figure 10), and hence cannot solely be explained through errors in the orbital parameters alone. There is a range in values present for the HyDRA-H retrievals, between $-0.84^{+0.17}_{-0.16} \text{ km s}^{-1}$ for MASCARA-4 b to $-6.87^{+0.17}_{-0.17} \text{ km s}^{-1}$ for WASP-76 b, as shown in Table 5. The constrained blueshifts are consistent with previous work exploring the Na signatures for a range of transiting hot and ultrahot Jupiters (Langeveld et al. 2022). From our constraints, we do not observe any significant trend in wind velocity across our sample of planets. Hence, further observations of the terminator at high resolution are needed to discern the driving mechanisms of the atmospheric dynamics.

Figure 10 also shows the constraints on the wind speeds for WASP-76 b and WASP-121 b for the first and last parts of the transit from the HyDRA-2D retrievals. This allows us to compare the wind profiles for each phase region. The results show that, for WASP-76 b, the wind speeds are much higher, and the profile has a much smaller spread for the latter part of the transit, in agreement with previous findings (Ehrenreich et al. 2020; Kesseli & Snellen 2021). Previous retrievals have shown that this could be driven by either the condensation of Fe on the morning and/or leading side or a high altitude opacity deck, which obscures the signal from this part of the atmosphere, with a slight preference for the latter (Gandhi et al. 2022). Hence, the signal is dominated by the more blueshifted evening (or trailing) side of the atmosphere, and thus the wind speeds are higher with a lower spread in the spectral signal. On the other hand, the retrievals for WASP-121 b indicate a more similar wind speed and δV_{wind} for the first and last parts of the transit. This may be due to the higher irradiation of WASP-121 b, resulting in a hot dayside where the Fe does not rain-out, and/or clouds do not form as readily in the photosphere. Our obtained wind speeds are also in agreement with the work by Maguire et al. (2023), who obtained values $\sim -6 \text{ km s}^{-1}$ for three separate transits of WASP-121 b.

The value of δV_{wind} , indicative of the spread in the profile, varies significantly across our sample. Three of the planets, MASCARA-4 b, MASCARA-2 b, and WASP-189 b, show

broader profiles for the wind speed distribution compared to the others. The larger spreads in the profiles of MASCARA-4 b and WASP-189 b could be driven by stellar residuals as these were the two planets in our sample where the RM effect significantly affected the planetary signal. While our RM correction allowed us to recover the planet’s signal, it clearly left both positive and negative residuals near the planet’s trace, which easily could cause the signal to appear broader. While MASCARA-2 b did not suffer from as much stellar contamination, this could still cause some amount of broadening. Previous studies using this same data set noted that the Fe I cross correlation profile appeared double peaked (e.g., Stangret et al. 2020), and with our 1D retrieval, a double peaked absorption profile could manifest as a large value of δV_{wind} . To fully understand what physical phenomenon is driving the blueshifts and line broadening, further analysis and data are required, which we leave for a subsequent study. For our study, we note that net blueshifts on the order of $\sim 1\text{--}7 \text{ km s}^{-1}$ seem ubiquitous in UHJ atmospheres.

3.6. Mass Constraints for MASCARA-2 b and HAT-P-70 b

For MASCARA-2 b and HAT-P-70 b, only an upper limit has been placed on the planetary mass, and hence we included the surface gravity, $\log(g)$, as an additional retrieval parameter for these two planets. The surface gravity of the planet has a strong influence on the strength of spectral features as it determines the scale height of the atmosphere, and previous studies have shown that transit observations can be used to extract the mass of the planet (de Wit & Seager 2013). For our retrievals of these two planets, we use a uniform prior of $\log(g) = [2, 7]$ (with g in centimeters per square second). For a given value of $\log(g)$, the corresponding mass M is

$$\frac{M}{M_J} \approx 4.0347 \times 10^{-4} \times 10^{\log(g)} \times \left(\frac{R_p}{R_J}\right)^2, \quad (8)$$

where R_p refers to the radius of the planet, and M_p and M_J refer to the radius and mass of Jupiter respectively.

Using our retrieved value of $\log(g)$, we derive the masses of $2.16^{+0.21}_{-0.22} M_J$ for MASCARA-2 b, and $1.66^{+0.20}_{-0.20} M_J$ for HAT-P-70 b. This is consistent with their upper limits of $<3.5 M_J$ and $<6.78 M_J$ respectively (Lund et al. 2017; Zhou et al. 2019). Hence, this method may be viable in providing mass constraints for exoplanets orbiting fast rotating stars such as MASCARA-2 b and HAT-P-70 b in the future. We tested the validity of this method by performing retrievals on the WASP-76 b ESPRESSO observations with $\log(g)$ as an additional retrieval parameter, and obtained a mass estimate of $0.84^{+0.06}_{-0.08} M_J$ for the $\phi = +0.02 - +0.04$ phase range, consistent with but slightly lower than the measured mass of $0.894^{+0.014}_{-0.013} M_J$ (Ehrenreich et al. 2020).

However, we note that this method of determining the planetary mass has degeneracies with the atmospheric temperature, as both the temperature and mass strongly influence the scale height. The method also relies on the assumption that the mean molecular weight of the atmosphere is determined, which for our case is assumed to be an atmosphere dominant in H and He. The recombination of H to H_2 in the atmosphere will reduce the scale height, and may result in the $\log(g)$ and hence the mass being overestimated if we assume an H/He-rich case. In addition, nonhydrostatic effects in the upper atmosphere can also influence the overall extent of spectral features and hence

bias the determined planet mass. Therefore, further independent verification of the masses of these two objects is needed to robustly test these biases further.

4. Conclusions

We retrieve the chemical abundances of eleven neutral atomic and molecular species in six UHJs through optical observations with the ESPRESSO and HARPS-N/HARPS spectrographs. We use the HyDRA-H and HyDRA-2D retrieval frameworks to perform retrievals of the terminator observations (Gandhi et al. 2019, 2022). From our retrieval survey, we find the following:

1. All of the planets show clear constraints on the atmospheric abundance of Fe given its high opacity and abundance, with values consistent with the stellar metallicity across the sample. This points to UHJs having at or near stellar abundances for refractory species, consistent with previous high-resolution studies (Pelletier et al. 2023) and previous work exploring alkali metals at low resolution (Welbanks et al. 2019).
2. In addition to Fe, we also retrieve for the abundances of Mg, Ni, Cr, Mn, V, Ca, Ti, TiO, TiH, and Na for each planet. Our abundance constraints for Mg, Ni, Cr, Mn, and V show a much greater variation across the sample of UHJs, with generally wider uncertainties or upper limits given their lower abundance and/or opacity. This highlights the challenge of using the abundance of a single species as a proxy for atmospheric metallicity, as these planets show significant compositional diversity.
3. Three species in our sample, Ca, Ti, and Na, show constraints and/or upper limits, which are below that expected if each species was present at stellar metallicity for all of the planets. However, chemical equilibrium models provide a good explanation as these are the species that are some of the most strongly ionized at high temperature and low pressure. Hence, the abundance of neutral species containing these atoms is reduced. For Ca and Ti, the retrievals do still indicate even lower abundances than suggested by chemical equilibrium, which may be caused by strong vertical chemical gradients for these species and/or the presence of CaTiO₃ clouds quenching these two species below the photosphere. We are able to constrain Ti and TiO for only WASP-189 b, the hottest planet in our sample, supporting the hypothesis of Ti being quenched on the nightsides of the other cooler planets.
4. We find that abundance ratios between species show tighter error bars than the absolute values for almost all species and planets, consistent with previous works (e.g., Gibson et al. 2022; Maguire et al. 2023; Pelletier et al. 2023). This near-universal finding across our sample indicates that HRS has an inherent strength in constraining the abundance ratios of species in exoplanet atmospheres. This arises because HRS is more sensitive to the relative line strengths between species given that the contribution from the spectral continuum is often removed and/or reduced during the analysis. This highlights the potential of using HRS for high-precision abundance ratio measurements, such as for refractory-to-volatile or C/O ratios. In addition, using low-resolution observations such as with Hubble Space Telescope and

JWST could be key in further constraining the abundances of trace species when used in tandem with HRS (Gandhi et al. 2019).

5. For two of the planets, WASP-76 b and WASP-121 b, we perform spatially resolved and separated-phase retrievals to explore the variation of each species in each region of the terminator. These retrievals show that the chemical abundances of each species at the terminator do not vary significantly and hence that there is no significant chemical asymmetry for most of the species. For both planets, we are able to retrieve Fe, Mg, Ni, Cr, Mn, V, and Ca in at least one part of the atmosphere, with the regions where they were not conclusively constrained generally showing upper limits consistent to the retrieved abundances in the detected regions. For WASP-76 b, we did constrain a lower abundance for Fe with a wider uncertainty for the less irradiated regions of the terminator, in agreement with previous work indicating that rain-out, cloud formation, and/or thermal differences between the leading and trailing limbs may be present (Ehrenreich et al. 2020; Wardenier et al. 2021; Gandhi et al. 2022; Savel et al. 2022).
6. In addition to the chemical abundances, we explored the atmospheric winds present on these planets through the wavelength shift and broadening of the planetary spectrum compared with the known orbital parameters. This Doppler shift arises as a result of winds in the upper atmosphere transporting material from the dayside to the nightside. From our retrievals, we find blueshifts with median values $\sim 2.3\text{--}9$ km s⁻¹, but with no significant trend across the sample of planets in our survey. For WASP-76 b, we constrain the highest wind speed for the end of the transit of $9.03_{-1.01}^{+1.03}$ km s⁻¹, but the first quarter of the transit shows a much lower $4.94_{-1.55}^{+1.62}$ km s⁻¹ velocity offset. This is consistent with previous observations and analyses (Ehrenreich et al. 2020; Kesseli & Snellen 2021; Wardenier et al. 2021; Gandhi et al. 2022).
7. We derive the masses of MASCARA-2 b and HAT-P-70 b by including a free parameter for the log(*g*) of the planets, constraining masses of $2.16_{-0.22}^{+0.21} M_J$ and $1.66_{-0.20}^{+0.20} M_J$ respectively. This is consistent with their upper limits in Table 1. This presents a potential way to determine the masses of planets around fast rotating stars, but we note that various degeneracies may exist in using the spectroscopic mass, and further work is needed to fully explore these biases.

Future work can expand the sample across a wider range of equilibrium temperatures and planet masses and radii in order to determine whether these trends vary across planetary system properties. The exoplanets with slightly cooler equilibrium temperatures nearer to 2000 K are of particular interest as many refractory species are expected to condense out of the atmosphere, and the transition between ultrahot Jupiters and hot Jupiters occurs (e.g., Fortney et al. 2008). Our retrievals could also be expanded to include ionic species in the atmosphere, as the chemical equilibrium models have shown that some species are significantly ionized at temperatures above ~ 2500 K. However, the ionization of atomic species is often a very strong function of pressure and may therefore require an abundance profile that varies with atmospheric altitude instead of our assumption of vertically homogeneous chemistry. The ionic species also often probe the exosphere,

which can make inferring abundances more challenging (e.g., Zhang et al. 2022; Maguire et al. 2023). In addition, we can also explore trends across the sample of planets in emission spectroscopy, which probe the hotter dayside and are more sensitive to the thermal profile of the atmosphere (e.g., Line et al. 2021; Cont et al. 2022; van Sluijs et al. 2023; Brogi et al. 2023).

Abundance constraints for the refractory species are of particular importance as they are expected to be accreted onto the planet as solids given their high sublimation temperatures, and hence provide a measure of the accreted rock during formation (Lothringer et al. 2021; Knierim et al. 2022; Chachan et al. 2023). Future work can combine these optical observations with those in the infrared such as JWST and ground-based observatories such as IGRINS/Gemini-S and CRIRES+/VLT, which can constrain volatile species. Such studies will provide important insights into the refractory-to-volatile ratios of exoplanets, allowing us to compare with carbon and oxygen bearing species to determine formation and migration scenarios (e.g., Öberg et al. 2011; Mordasini et al. 2016). For such retrievals, the vertically homogeneous chemistry assumptions may also need to be relaxed as abundances of species such as H₂O are strong functions of pressure (Parmentier et al. 2018), and can otherwise lead to biased retrieved estimates (Pluriel et al. 2022).

This work demonstrates the similarities and differences in the chemical abundances in our sample of ultrahot Jupiters. Furthermore, the high-resolution observations are sensitive to atmospheric winds, which transport thermal energy and material between the dayside and nightside, resulting in a net

blueshift of the spectrum, which we are able to clearly constrain for the planets in our sample. High-resolution spectroscopy will therefore play a key role in exploring atmospheric chemistry and dynamics on exoplanets in upcoming years, in particular with the next generation of large ground-based facilities such as the Extremely Large Telescope (Maiolino et al. 2013).

Appendix A Condensation Temperatures for Refractory Species

Table 3 shows the condensation temperatures for a range of species that are expected to form in the atmospheres of UHJs.

Table 3
Condensation Temperatures for the Refractory Species in Our Work

Species	Condensate	P - T Relation	$T(0.1\text{mbar})/\text{K}$	Reference
Ca/Ti	CaTiO ₃	$\frac{10^4}{T} = 5.125 - 0.277 \log(P) - 0.554[\text{Fe}/\text{H}]$	1604	Wakeford et al. (2017)
Fe	Fe	$\frac{10^4}{T} = 5.44 - 0.48 \log(P) - 0.48[\text{Fe}/\text{H}]$	1359	Visscher et al. (2010)
Mg	Mg ₂ SiO ₄	$\frac{10^4}{T} = 5.89 - 0.37 \log(P) - 0.73[\text{Fe}/\text{H}]$	1357	Visscher et al. (2010)
Mg	MgSiO ₃	$\frac{10^4}{T} = 6.26 - 0.35 \log(P) - 0.70[\text{Fe}/\text{H}]$	1305	Visscher et al. (2010)
Cr	Cr	$\frac{10^4}{T} = 6.576 - 0.486 \log(P) - 0.486[\text{Fe}/\text{H}]$	1174	Morley et al. (2012)
Mn	MnS	$\frac{10^4}{T} = 7.45 - 0.42 \log(P) - 0.84[\text{Fe}/\text{H}]$	1095	Visscher et al. (2006)
Na	Na ₂ S	$\frac{10^4}{T} = 10.05 - 0.72 \log(P) - 1.08[\text{Fe}/\text{H}]$	774	Visscher et al. (2006)

Note. The third column shows the P - T relation of the condensation curve, with the temperature T in kelvins, the pressure P in bar, and the metallicity of the atmosphere $[\text{Fe}/\text{H}]$.

Appendix B Temperature Profiles

Constraints on the temperature profiles from our retrievals for each planet, shown in Figure 11.

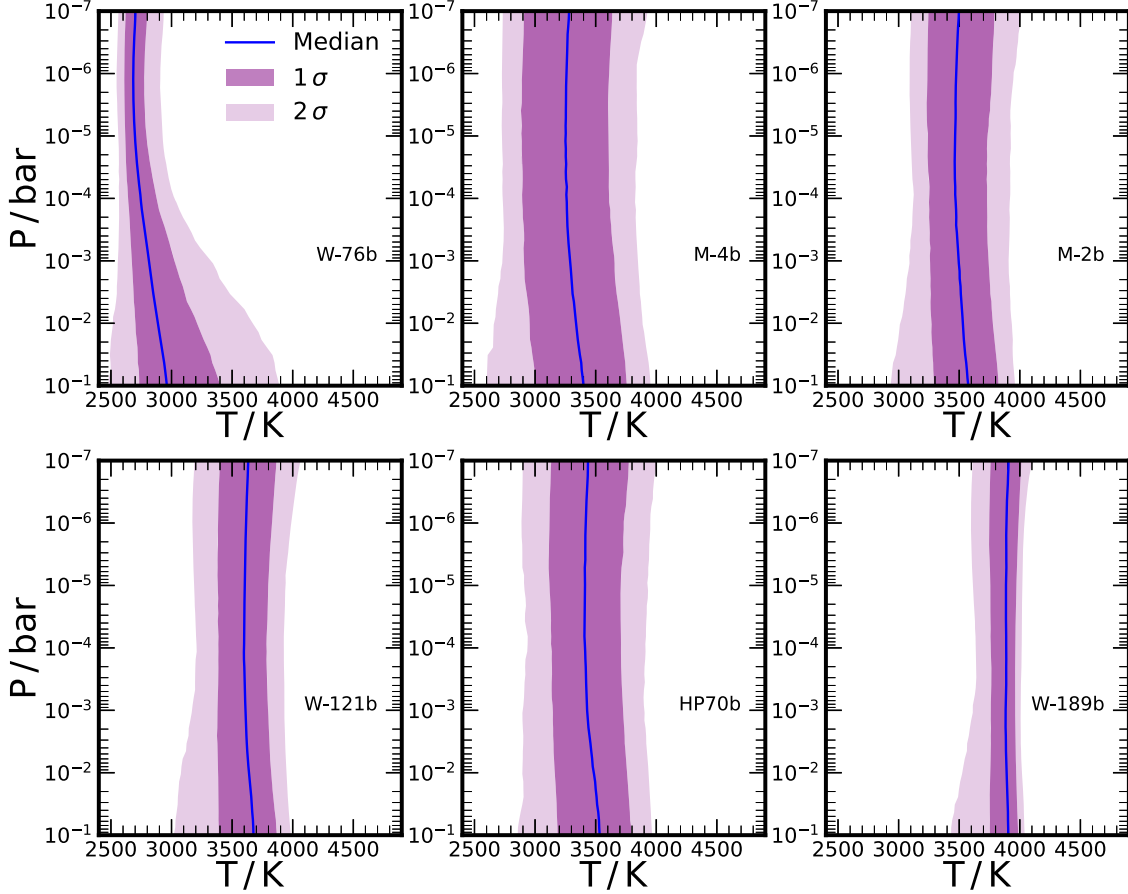

Figure 11. Retrieved temperature profiles for the HyDRA-H retrievals for each of the planets in our survey. The median profile is given by the blue line, with the darker and lighter shades of purple indicating the 1σ and 2σ confidence ranges respectively.

Appendix C Relative Abundances

Table 4 shows the constraints on the relative abundance of each species against Fe.

Table 4
Values of $\varphi_{X,Fe}$ and 1σ Errors for Each Species X for the Planets in Our Survey

Species	WASP-76 b	MASCARA-4 b	MASCARA-2 b	WASP-121 b	HAT-P-70 b	WASP-189 b
Mg	$0.57^{+0.33}_{-0.37}$	$0.33^{+0.16}_{-0.15}$	$0.27^{+0.18}_{-0.2}$	$-1.35^{+0.66}_{-0.9}$	$0.74^{+0.31}_{-0.33}$	$0.24^{+0.22}_{-0.24}$
Ni	$0.69^{+0.17}_{-0.17}$	$-0.16^{+0.21}_{-0.25}$	< -0.08	$0.85^{+0.27}_{-0.28}$	< 0.66	$0.57^{+0.2}_{-0.15}$
Cr	$-1.16^{+0.16}_{-0.19}$	$-2.81^{+0.23}_{-0.27}$	$-1.28^{+0.21}_{-0.24}$	$-0.71^{+0.26}_{-0.26}$	$-1.25^{+0.36}_{-0.41}$	$-0.42^{+0.14}_{-0.15}$
Mn	$0.36^{+0.13}_{-0.14}$	$-1.82^{+0.28}_{-0.32}$	$-0.63^{+0.25}_{-0.28}$	< -1.78	$0.36^{+0.32}_{-0.35}$	$-0.74^{+0.31}_{-0.34}$
V	$-0.57^{+0.14}_{-0.15}$	$-2.06^{+0.2}_{-0.24}$	< -2.7	$-0.24^{+0.17}_{-0.17}$	$-0.65^{+0.25}_{-0.27}$	$-1.69^{+0.4}_{-0.46}$
Ca	$-3.14^{+0.19}_{-0.22}$	$-2.81^{+0.14}_{-0.16}$	$-2.45^{+0.17}_{-0.19}$	$-2.74^{+0.24}_{-0.25}$	$-2.86^{+0.31}_{-0.38}$	$-2.23^{+0.15}_{-0.16}$
Ti ^a	< -2.66	< -2.81	< -1.67	< -2.16	< -2.13	$-1.48^{+0.13}_{-0.16}$
Na	< -1.63	< -2.61	< -2.0	< -1.52	< -2.02	< -2.27

Notes. Where no significant constraints were retrieved, we show the 2σ upper limit.

^a Ti value is the sum of the constraints for atomic Ti, and molecular TiO and TiH.

Appendix D Constraints on Winds

Table 5 shows the phase ranges used for our retrievals and the constraints on the winds.

Table 5

Phase Ranges and Wind Constraints for Each of the Planets in Our Survey

Planet	ϕ Range	$\Delta V_{\text{sys}}/$ km s ⁻¹	$\delta V_{\text{wind}}/\text{km s}^{-1}$
WASP-76 b	-0.04 – -0.02, +0.02 – +0.04	$-6.87^{+0.17}_{-0.17}$	$6.93^{+0.55}_{-0.55}$
	2D -0.04 – -0.02	$-4.94^{+1.62}_{-1.55}$	$11.58^{+0.97}_{-0.93}$
	2D +0.02 – +0.04	$-9.03^{+1.03}_{-1.01}$	$6.46^{+0.55}_{-0.56}$
MASCARA-4 b	-0.03 – -0.015, +0.00 – +0.01	$-0.84^{+0.4}_{-0.16}$	$10.14^{+0.4}_{-0.43}$
	MASCARA-2 b	-0.022 – -0.005, +0.005 – +0.022	$-2.97^{+0.32}_{-0.36}$
WASP-121 b	-0.0475 – -0.02, +0.02 – +0.0475	$-5.58^{+0.4}_{-0.44}$	$7.92^{+1.1}_{-1.31}$
	2D -0.0475 – -0.02	$-7.37^{+1.46}_{-1.34}$	$4.02^{+1.39}_{-1.46}$
	2D +0.02 – +0.0475	$-4.33^{+1.72}_{-1.57}$	$4.75^{+1.52}_{-1.64}$
HAT-P-70 b	-0.01 – +0.025	$-6.7^{+0.29}_{-0.29}$	$4.59^{+1.23}_{-1.28}$
WASP-189 b	-0.033 – +0.02	$-2.33^{+0.5}_{-0.5}$	$23.59^{+1.1}_{-1.19}$

Note. The right 2 columns give the constraints on ΔV_{sys} and δV_{wind} and their 1σ errors. For WASP-76 b and WASP-121 b, we also show the constraints from the HyDRA-2D retrievals on each of the separate phase ranges.
